## COLOR CODING

*Ophthalmology* is organized into 12 parts, which are color-coded as follows for quick and easy reference:

Part 1: Genetics
Part 2: Optics and Refraction
Part 3: Refractive Surgery
Part 4: Cornea and Ocular Surface Diseases
Part 5: The Lens
Part 6: Retina and Vitreous
Part 7: Uveitis and Other Intraocular Inflammations
Part 8: Intraocular Tumors
Part 9: Neuro-Ophthalmology
Part 10: Glaucoma
Part 11: Pediatric and Adult Strabismus
Part 12: Orbit and Oculoplastics

## EXPERTCONSULT WEBSITE

- Full searchable text and downloadable image gallery
- Full reference lists for each chapter
- Additional online content including text, figures, & video clips

# Video Contents

## Part 3: Refractive Surgery

### Chapter 3.4 LASIK

- 3.4.1 iLASIK

### Chapter 3.5 Small Incision Lenticule Extraction (SMILE)

- 3.5.1 SMILE Instructional Video

### Chapter 3.7 Phakic Intraocular Lenses

- 3.7.1 Cachet Lens  
3.7.2 Artisan/Verisyse Lens Implantation for Hyperopia After Radial Keratotomy  
3.7.3 Toric Artiflex Phakic Intraocular Lens in a Patient With High Myopia and Astigmatism After Deep Anterior Lamellar Keratoplasty  
3.7.4 Toric Artiflex Lens Implantation in a Patient With a Previous Intracorneal Ring for Keratoconus  
3.7.5 ICL Implantation  
3.7.6 ICL Exchange

## Part 4: Cornea and Ocular Surface Diseases

### Chapter 4.17 Noninfectious Keratitis

- 4.17.1 Patient With Lax Eyelids Recommended for Sleep Study

### Chapter 4.29 Endothelial Keratoplasty: Targeted Treatment for Corneal Endothelial Dysfunction

- 4.29.1 DSEK Pull-Through  
4.29.2 DMEK Donor Preparation  
4.29.3 Descemet's Membrane Endothelial Keratoplasty (DMEK)

## Part 5: The Lens

### Chapter 5.8 Anesthesia for Cataract Surgery

- 5.8.1 Standard Technique for Sub-Tenon's Anesthesia  
5.8.2 "Incisionless" Technique for Sub-Tenon's Anesthesia

### Chapter 5.9 Phacoemulsification

- 5.9.1 Two Examples of "Sculpting" Using Low Flow and Vacuum but Higher Power/Amplitude  
5.9.2 Two Examples of Using Higher Flow and Vacuum for Nucleus Fragment Removal

### Chapter 5.11 Small Incision and Femtosecond Laser-Assisted Cataract Surgery

- 5.11.1 Unexpected Subluxation  
5.11.2 Microincision Phaco  
5.11.3 Microincision Refractive Lens Exchange  
5.11.4 700μ Phaco

### Chapter 5.13 Combined Procedures

- 5.13.1 Combined Phacoemulsification Cataract Surgery and Descemet's Stripping Automated Endothelial Keratoplasty (DSAEK)  
5.13.2 Combined Phacovitrectomy

### Chapter 5.16 Complications of Cataract Surgery

- 5.16.1 Artisan Implantation

## Part 6: Retina and Vitreous

### Chapter 6.3 Retinal and Choroidal Circulation

- 6.3.1 Fluorescein and Indocyanine Green (ICG) Video Angiogram

### Chapter 6.5 Contact B-Scan Ultrasonography

- 6.5.1 Examination Techniques for Contact B-Scan Ultrasonography

### Chapter 6.11 Scleral Buckling Surgery

- 6.11.1 Scleral Buckle  
6.11.2 Suture  
6.11.3 Drain

### Chapter 6.12 Vitrectomy

- 6.12.1 Vitrectomy for Nonclearing Vitreous Hemorrhage

### Chapter 6.25 Coats' Disease and Retinal Telangiectasia

- 6.25.1 Pars Plana Vitrectomy and Subretinal Fluid and Exudate Drainage Performed for a Severe Exudative Retinal Detachment

### Chapter 6.32 Macular Hole

- 6.32.1 Macular Hole Surgery

### Chapter 6.33 Epiretinal Membrane

- 6.33.1 Epiretinal Membrane Removal

### Chapter 6.34 Vitreomacular Traction

- 6.34.1 Vitreomacular Traction Syndrome

### Chapter 6.39 Rhegmatogenous Retinal Detachment

- 6.39.1 Internal Limiting Membrane (ILM) Peeling for Primary Rhegmatogenous Repair to Reduce Postoperative Macular Pucker

### Chapter 6.41 Choroidal Hemorrhage

- 6.41.1 Transconjunctival Trocar/Cannula Drainage of Suprachoroidal Fluid

### Chapter 6.43 Posterior Segment Ocular Trauma

- 6.43.1 Intraocular Foreign Body Removal  
6.43.2 Intraocular Foreign Body Removal With Rare Earth Magnet

## Part 9: Neuro-Ophthalmology

### Chapter 9.19 Nystagmus, Saccadic Intrusions, and Oscillations

- 9.19.1 Congenital Nystagmus  
9.19.2 Oculocutaneous Albinism With Associated Nystagmus  
9.19.3 Latent Nystagmus  
9.19.4 Spasmus Nutans  
9.19.5 Right Internuclear Ophthalmoplegia  
9.19.6 Convergence Retraction Nystagmus in Parinaud's Syndrome

## Part 10: Glaucoma

### Chapter 10.7 Optic Nerve Analysis

- 10.7.1 Three-Dimensional Imaging of the Optic Nerve Head

### Chapter 10.28 Minimally Invasive and Microincisional Glaucoma Surgeries

- 10.28.1 iStent G1 Implantation  
10.28.2 Key Steps in Trabectome Surgery

### Chapter 10.29 Trabeculectomy

- 10.29.1 Bleb Leak Detection Using Concentrated Fluorescein Dye  
10.29.2 Trabeculectomy With Mitomycin C  
10.29.3 5-Fluorouracil Subconjunctival Injection

### Chapter 10.32 Complications of Glaucoma Surgery and Their Management

- 10.32.1 Small Pupil Cataract Surgery With Use of Pupil Expansion Ring (I-Ring; Beaver Visitec, Waltham, MA) and Trypan Blue Capsular Staining  
10.32.2 Repair of Bleb Leak

## Part 11: Pediatric and Adult Strabismus

### Chapter 11.3 Examination of Ocular Alignment and Eye Movements

- 11.3.1 Strabismus Exam Elements  
11.3.2 Cover/Uncover Test  
11.3.3 Exotropia  
11.3.4 Esotropia  
11.3.5 Hypertropia  
11.3.6 Prism Alternate Cover Test  
11.3.7 Simultaneous Prism Cover Test  
11.3.8 Exophoria  
11.3.9 Alternate or Cross Cover Test

Total running time approximately 2 hours and 34 minutes

# Preface

It's been 20 years since the first edition of *Ophthalmology* was published. We are delighted that our textbook now has gone to a fifth edition. The longevity of this title reflects the uniqueness and utility of its format; the hard work of our authors, editors, and publishers; and the pressing need in our field for updated, clinically relevant information. We continue to recognize the advantage of a complete textbook of ophthalmology in a single volume rather than multiple volumes. The basic visual science is admixed with clinical information throughout, and we have maintained an entire separate section dedicated to genetics and the eye.

*Ophthalmology* was never intended to be encyclopedic, but with each edition we strived to make it quite comprehensive, readable, and easy to access. Like the fourth edition, this edition is thoroughly revised, with new section editors and many new authors. Chapters have been rewritten and restricted to reflect the new way diseases are diagnosed, categorized, and treated. We have discarded out-of-date material and have added numerous new items. Extra references and other material have been moved online to keep the book itself as one volume.

# Preface to First Edition

Over the past 30 years, enormous technologic advances have occurred in many different areas of medicine—lasers, molecular genetics, and immunology to name a few. This progress has fueled similar advances in almost every aspect of ophthalmic practice. The assimilation and integration of so much new information makes narrower and more focused ophthalmic practices a necessity. As a direct consequence, many subspecialty textbooks with extremely narrow focus are now available, covering every aspect of ophthalmic practice. Concurrently, several excellent multivolume textbooks detailing all aspects of ophthalmic practice have been developed. Yet there remains a need for a complete single-volume textbook of ophthalmology for trainees, nonophthalmologists, and those general ophthalmologists (and perhaps specialists) who need an update in specific areas in which they do not have expertise. *Ophthalmology* was created to fill this void between the multivolume and narrow subspecialty book.

This book is an entirely new, comprehensive, clinically relevant, single-volume textbook of ophthalmology, with a new approach to content and presentation that allows the reader to access key information quickly. Our approach, from the outset, has been to use templates to maintain a uniform chapter structure throughout the book so that the material is presented in a logical, consistent manner, without repetition. The majority of chapters in the book follow one of three templates: the disease-oriented template, the surgical procedure template, or the diagnostic testing template. Meticulous planning went into the content, sectioning, and chapter organization of the book, with the aim of presenting ophthalmology as it is practiced, rather than as a collection of artificially divided aspects. Thus, pediatric ophthalmology is not in a separate section but is integrated into relevant sections across the book. The basic visual science and clinical information, including systemic manifestations, is integrated throughout, with only two exceptions. We dedicated an entire section to genetics and the eye, in recognition of the increasing importance of genetics in ophthalmology. Optics and refraction are included in a single section as well because an understanding of these subjects is fundamental to all of ophthalmology.

To achieve the same continuity of presentation in the figures as well as in the text, all of the artworks have been redesigned from the authors' originals, maximizing their accessibility for the reader. Each section is color coded for easy cross-referencing and navigation through the book. Despite the extensive use of color in artworks and photographs throughout, the cost of this comprehensive book has been kept to a fraction of the multivolume sets. We hope to make this volume more accessible to more practitioners throughout the world.

Although comprehensive, *Ophthalmology* is not intended to be encyclopedic. In particular, in dealing with surgery, we do not stress specific techniques or describe rarer ones in meticulous detail. The rapidly changing nature of surgical aspects of ophthalmic practice is such that the reader will need to refer to one or more of the plethora of excellent books that cover specific current techniques in depth. We concentrate instead on the areas that are less volatile but, nevertheless, vital surgical indications, general principles of surgical technique, and complications. The approach to referencing is parallel to this: For every topic, all the key references are listed, but with the aim of avoiding pages of redundant references where a smaller number of recent classic reviews will suffice. The overall emphasis of *Ophthalmology* is current information that is relevant to clinical practice superimposed on the broad framework that comprises ophthalmology as a subspecialty.

Essential to the realization of this ambitious project is the team of Section Editors, each bringing unique insight and expertise to the book. They have coordinated their efforts in shaping the contents list, finding contributors, and editing chapters to produce a book that we hope will make a great contribution to ophthalmology.

We are grateful to the editors and authors who have contributed to *Ophthalmology* and to the superb, dedicated team at Mosby.

Myron Yanoff

Adjunct Professor  
Department of Ophthalmology and  
Visual Sciences  
Escola Paulista de Medicina (EPM)  
Universidade Federal de São Paulo  
(UNIFESP)  
São Paulo, SP, Brazil

**Chi-Chao Chan, MD**  
Scientist Emeritus  
Laboratory of Immunology  
National Eye Institute  
National Institutes of Health  
Bethesda, MD, USA  
Visiting Professor  
Zhongshan Ophthalmic Center  
Sun Yat-Sen University  
China

**Melinda Y. Chang, MD**  
Assistant Professor of Ophthalmology  
USC Roski Eye Institute and Children's  
Hospital Los Angeles  
Keck School of Medicine of the  
University of Southern California  
Los Angeles, CA, USA

**Stanley Chang, MD**  
KK Tse and KT Ying Professor of  
Ophthalmology  
Department of Ophthalmology  
Columbia University  
New York, NY, USA

**Victoria S. Chang, MD**  
Assistant Professor of Clinical  
Ophthalmology  
Ophthalmology, Cornea and External  
Disease  
Bascom Palmer Eye Institute  
University of Miami  
Naples, FL, USA

**David G. Charteris, MD, FRCS(Ed), FRCOphth**  
Professor  
Vitreoretinal Unit  
Moorfields Eye Hospital  
London, UK

**Soon-Phaik Chee, MD**  
Professor  
Cataract Service, Ocular Inflammation  
& Immunology Service  
Singapore National Eye Centre  
Singapore

**John J. Chen, MD, PhD**  
Assistant Professor  
Department of Ophthalmology and  
Neurology  
Mayo Clinic  
Rochester, MN, USA

**Xuejing Chen, MD, MS**  
Clinical Fellow  
Retina  
Ophthalmic Consultants of Boston  
New England Eye Center at Tufts  
Medical Center  
Boston, MA, USA

**Paul T.K. Chew, MMed, FRCOphth**  
Director Glaucoma Division  
Ophthalmology/Glaucoma  
National University Hospital Singapore  
Singapore

**Bing Chiu, MD**  
Ophthalmology Resident  
New York University  
New York, NY, USA

**Clement C. Chow, MD**  
Partner Physician  
Retinal Diagnostic Center  
Campbell, CA, USA

**Mortimer M. Civan, MD**  
Professor of Physiology and Professor  
of Medicine  
Department of Physiology  
University of Pennsylvania  
Perelman School of Medicine  
Philadelphia, PA, USA

**Abbot (Abe) Clark, PhD, FARVO**  
Regents Professor of Pharmacology  
and Neuroscience  
Executive Director, North Texas Eye  
Research Institute  
University of North Texas Health  
Science Center  
Fort Worth, TX, USA

**Jonathan C.K. Clarke, MD, FRCOphth**  
Consultant Ophthalmologist  
NIHR Moorfields Biomedical Research  
Centre  
Moorfields Eye Hospital  
UCL Institute of Ophthalmology  
London, UK

**François Codère, MD**  
Associate Professor  
Ophthalmology/Oculoplastic and  
Orbital Surgery Section  
Université de Montréal  
Montréal, QC, Canada

**Ian P. Conner, MD, PhD**  
Assistant Professor  
Ophthalmology  
UPMC Eye Center  
Pittsburgh, PA, USA

**Peter Coombs, MD**  
Vitreoretinal Physician and Surgeon  
Utah Eye Centers  
Salt Lake City, UT, USA

**Zélia M. Corrêa, MD, PhD**  
Tom Clancy Endowed Professor of  
Ophthalmology  
Head of Ocular Oncology and  
Echography  
Retina Service, Wilmer Eye Institute  
Johns Hopkins University School of  
Medicine  
Baltimore, MD, USA

**Steven M. Couch, MD, FACS**  
Assistant Professor  
Department of Ophthalmology &  
Visual Sciences  
Washington University in St Louis  
St Louis, MO, USA

**Stuart G. Coupland, PhD**  
Associate Professor  
Department of Ophthalmology  
University of Ottawa  
Ottawa, ON, Canada

**Claude L. Cowan, Jr., MD, MPH**  
Clinical Professor of Ophthalmology  
Georgetown University Medical Center  
Washington, DC, USA  
Staff Physician  
Surgical Service  
Veterans Affairs Medical Center  
Washington, DC, USA

**E. Randy Craven, MD**  
Associate Professor, Glaucoma  
Johns Hopkins University  
Baltimore, MD, USA

**Catherine A. Cukras, MD, PhD**  
Director, Medical Retina Fellowship  
Program  
National Eye Institute  
National Institutes of Health  
Bethesda, MD, USA

**Linda R. Dagi, MD**  
Director of Adult Strabismus  
Boston Children's Hospital  
Associate Professor of Ophthalmology  
Director of Quality Assurance  
Department of Ophthalmology  
Children's Hospital Ophthalmology  
Foundation Chair  
Harvard Medical School  
Boston, MA, USA

**Elie Dahan, MD, MMed, (Ophth)<sup>†</sup>**

Formerly Senior Consultant Pediatric  
Ophthalmology and Glaucoma  
Department of Ophthalmology  
Ein Tal Eye Hospital  
Tel Aviv, Israel

**Iben Bach Damgaard, MD**

PhD Fellow  
Department of Ophthalmology  
Aarhus University Hospital  
Aarhus, Denmark

**Karim F. Damji, MD, FRCSC, MBA**

Professor  
Department of Ophthalmology &  
Visual Sciences  
University of Alberta  
Edmonton, AL, Canada

**Dipankar Das, MD**

Senior Consultant & Ocular Pathologist  
Uveitis, Ocular Pathology and Neuro-  
ophthalmology Services  
Sri Sankaradeva Nethralaya  
Guwahati, Assam, India

**Adam DeBusk, DO, MS**

Instructor  
Department of Ophthalmology  
Wills Eye Hospital  
Sidney Kimmel Medical College  
Thomas Jefferson University  
Philadelphia, PA, USA

**Jose de la Cruz, MD, MSc**

Assistant Professor  
Ophthalmology, Cornea Refractive  
Surgery Service  
University of Illinois Eye and Ear  
Infirmiry  
Chicago, IL, USA

**Joseph L. Demer, MD, PhD**

Arthur L. Rosenbaum Chair in  
Pediatric Ophthalmology  
Professor of Neurology  
Chief, Pediatric Ophthalmology and  
Strabismus Division  
Director, Ocular Motility Laboratories  
Chair, EyeSTAR Residency/PhD and  
Post-doctoral Fellowship Program in  
Ophthalmology and Visual Science  
Member, Neuroscience  
Interdepartmental Program  
Member, Bioengineering  
Interdepartmental Program  
University of California Los Angeles  
Los Angeles, CA, USA

**Shilpa J. Desai, MD**

Assistant Professor  
Department of Ophthalmology  
Tufts University  
School of Medicine  
Boston, MA, USA

**Deepinder K. Dhaliwal, MD, LAc**

Professor of Ophthalmology, University  
of Pittsburgh School of Medicine  
Director, Cornea and Refractive  
Surgery Services  
Director and Founder, Center for  
Integrative Eye Care  
Co-Director, Cornea and Refractive  
Surgery Fellowship  
Associate Medical Director, Charles  
T. Campbell Ocular Microbiology  
Laboratory  
Medical Director, UPMC Laser Vision  
Center  
University of Pittsburgh Medical  
Center  
Pittsburgh, PA, USA

**Gary R. Diamond, MD<sup>†</sup>**

Formerly Professor of Ophthalmology  
and Pediatrics  
Drexel University School of Medicine  
Philadelphia, PA, USA

**Daniel Diniz, MD**

Surgical Optics Fellow  
Department of Ophthalmology &  
Visual Sciences  
Federal University of São Paulo  
(UNIFESP)  
São Paulo, SP, Brazil

**Diana V. Do, MD**

Professor of Ophthalmology  
Byers Eye Institute  
Stanford University  
School of Medicine  
Palo Alto, CA, USA

**Peter J. Dolman, MD, FRCSC**

Clinical Professor  
Division Head of Oculoplastics and  
Orbital Surgery  
Fellowship Director  
Department of Ophthalmology &  
Visual Sciences  
Division of Oculoplastics and Orbit  
University of British Columbia  
Vancouver General Hospital  
Vancouver, BC, Canada

**Sean P. Donahue, MD, PhD**

Professor  
Department of Ophthalmology &  
Visual Sciences  
Vanderbilt University  
Nashville, TN, USA

**Richard K. Dortzbach, MD**

Professor Emeritus  
Department of Ophthalmology and  
Visual Sciences  
University of Wisconsin  
School of Medicine and Public Health  
Madison, WI, USA

**Kimberly A. Drenser, MD, PhD**

Associated Retinal Consultants, PC  
Department of Ophthalmology  
Oakland University  
William Beaumont Hospital School of  
Medicine  
Royal Oak, MI, USA

**Jacob S. Duker, MD**

Resident Physician  
Department of Ophthalmology  
Bascom Palmer Eye Institute  
University of Miami  
Miami, FL, USA

**Jay S. Duker, MD**

Director  
New England Eye Center  
Professor and Chairman  
Department of Ophthalmology  
Tufts Medical Center  
Tufts University School of Medicine  
Boston, MA, USA

**Vikram D. Durairaj, MD, FACS**

ASOPRS Fellowship Director and  
Managing Partner  
Oculoplastic and Orbital Surgery  
TOC Eye and Face  
Austin, TX, USA

**Jonathan J. Dutton, MD, PhD**

Professor Emeritus  
Department of Ophthalmology  
University of North Carolina  
Chapel Hill, NC, USA

**Bryan Edgington, MD**

Associate Professor, Cornea Division  
Casey Eye Institute  
Oregon Health Sciences University  
Staff Ophthalmologist  
Veterans Health Administration  
Portland Health Care System  
Portland, OR, USA

**Howard M. Eggers, MD**

Professor of Clinical Ophthalmology  
Harkness Eye Institute  
New York, NY, USA

**Dean Elliott, MD**

Stelios Evangelos Gragoudas Associate  
Professor of Ophthalmology  
Harvard Medical School  
Associate Director, Retina Service  
Massachusetts Eye & Ear  
Boston, MA, USA

**George S. Ellis, Jr., MD, FAAP, FAAO, FACS**

Director Ophthalmology  
Children's Hospital New Orleans  
Associate Clinical Professor of  
Ophthalmology and Pediatrics  
Tulane University  
Associate Clinical Professor of  
Ophthalmology and Pediatrics  
Louisiana State Universities Schools of  
Medicine  
New Orleans, LA, USA

**Michael Engelbert, MD, PhD**

Research Assistant Professor  
Department of Ophthalmology  
NYU/VRMNY  
New York, NY, USA

**Miriam Englander, MD**

Attending Surgeon  
Vitreoretinal Surgery  
Ophthalmic Consultants of Boston  
Boston, MA, USA

**Bitá Esmaeli, MD, FACS**

Professor of Ophthalmology  
Director, Ophthalmic Plastic &  
Reconstructive Surgery Fellowship  
Program, Department of Plastic  
Surgery  
Chair, Graduate Medical Education  
Committee  
University of Texas MD Anderson  
Cancer Center  
Houston, TX, USA

**Joshua W. Evans, MD**

Assistant Professor of Ophthalmology  
Division of Glaucoma  
University of Kentucky  
Lexington, KY, USA

**Monica Evans, MD**

Ophthalmology  
San Jose, Costa Rica

**Daoud S. Fahd, MD**

Clinical Assistant Professor  
Department of Ophthalmology  
Ophthalmic Consultants of Beirut  
Jal el Dib, Metn, Lebanon

**Lisa J. Faia, MD**

Partner, Associated Retinal Consultants  
Associate Professor  
Oakland University  
William Beaumont School of Medicine  
Ophthalmology - Retina  
Royal Oak, MI, USA

**Katherine A. Fallano, MD**

Department of Ophthalmology  
University of Pittsburgh School of  
Medicine  
Pittsburgh, PA, USA

**Ayad A. Farjo, MD**

President & Director  
Brighton Vision Center  
Brighton, MI, USA

**Eric Feinstein, MD**

Surgical Retina Fellow  
Department of Ophthalmology  
Rocky Mountain Lions Eye Institute  
University of Colorado  
School of Medicine  
Denver, CO, USA

**Karen B. Fernandez, MD**

Consultant  
Department of Ophthalmology  
The Medical City  
Pasig City, Metro Manila, Philippines

**Yale L. Fisher, MD**

Voluntary Clinical Professor  
Department of Ophthalmology  
Bascom Palmer Eye Institute  
Miami, FL, USA  
Voluntary Clinical Professor  
Department of Ophthalmology  
Weill Cornell Medical Center  
New York, NY, USA

**Gerald A. Fishman, MD**

Director  
The Pangere Center for Inherited  
Retinal Diseases  
The Chicago Lighthouse  
Professor Emeritus of Ophthalmology  
Department of Ophthalmology &  
Visual Sciences  
University of Illinois at Chicago  
College of Medicine  
Chicago, IL, USA

**Jorge A. Fortun, MD**

Associate Professor of Ophthalmology  
Vitreoretinal Diseases and Surgery  
Medical Director of Bascom Palmer  
Eye Institute  
Palm Beach Gardens Bascom Palmer  
Eye Institute  
University of Miami Miller School of  
Medicine  
Miami, FL, USA

**Veronica Vargas Fragoso, MD**

Refractive Surgery Fellow  
Vissum Corporation  
Alicante, Spain

**Nicola Freeman, MBChB, FCophth, MMed**

Senior Specialist  
Department of Pediatric  
Ophthalmology  
Red Cross Children's Hospital  
Cape Town, Western Province, South  
Africa

**David S. Friedman, MD, MPH, PhD**

Director, Dana Center for Preventive  
Ophthalmology  
Professor of Ophthalmology, Wilmer/  
Glaucoma  
Johns Hopkins University  
Baltimore, MD, USA

Research Fellow  
Department of Ophthalmology and  
Center for Translational Ocular  
Immunology  
Tufts Medical Center  
New England Eye Center  
Boston, MA, USA  
PhD Candidate  
Department of Ophthalmology  
Universidade Federal de São Paulo  
(UNIFESP)  
São Paulo, SP, Brazil

**L. Jay Katz, MD**  
Director, Glaucoma Service  
Wills Eye Hospital  
Philadelphia, PA, USA

**Paul L. Kaufman, MD**  
Ernst H. Bárány Professor of Ocular  
Pharmacology  
Department Chair Emeritus  
Department of Ophthalmology &  
Visual Sciences  
University of Wisconsin-Madison  
School of Medicine & Public Health  
Madison, WI, USA

**Jeremy D. Keenan, MD, MPH**  
Associate Professor of Ophthalmology  
Francis I. Proctor Foundation and  
Department of Ophthalmology  
University of California San Francisco  
San Francisco, CA, USA

**Kenneth R. Kenyon, MD**  
Clinical Professor, Ophthalmology  
Tufts University  
School of Medicine  
Harvard Medical School  
Schepens Eye Research Institute  
Boston, MA, USA

**Sir Peng Tee Khaw, PhD, FRCS, FRCP, FRCOphth, FRCPath, FRSB, FCOptom (Hon), DSc, FARVO, FMedSci**  
Professor of Glaucoma and Ocular  
Healing  
Consultant Ophthalmic Surgeon  
Director, National Institute for Health  
Research, Biomedical Research  
Centre for Ophthalmology  
Moorfields Eye Hospital  
UCL Institute of Ophthalmology  
London, UK

**Gene Kim, MD**  
Assistant Professor and Residency  
Program Director  
Department of Ophthalmology &  
Visual Science at McGovern Medical  
School at UTHealth  
Houston, TX, USA

**Ivana K. Kim, MD**  
Associate Professor of Ophthalmology  
Retina Service, Massachusetts Eye and  
Ear  
Harvard Medical School  
Boston, MA, USA

**Alan E. Kimura, MD, MPH**  
Clinical Associate Professor  
Department of Ophthalmology  
University of Colorado  
Health Sciences Center  
Aurora, CO, USA

**Michael Kinori, MD**  
Senior Physician  
The Goldschleger Eye Institute  
Sheba Medical Center, Tel Hashomer  
Ramat Gan, Israel

**Caitriona Kirwan, FRCSI(Ophth)**  
Consultant Ophthalmic Surgeon  
Mater Private Hospital  
Dublin, Ireland

**Szilárd Kiss, MD**  
Chief, Retina Service Director  
Clinical Research Director  
Tele-Ophthalmology Director  
Compliance Associate Professor of  
Ophthalmology  
Weill Cornell Medical College  
New York, NY, USA

**John W. Kitchens, MD**  
Retina Surgeon, Partner  
Co-Fellowship Director  
Retina Associates of Kentucky  
Lexington, KY, USA

**Kendra Klein, MD**  
Faculty Physician  
Department of Ophthalmology  
University of Arizona  
Associated Retina Consultants  
Phoenix, AZ, USA

**Douglas D. Koch, MD**  
Professor and Allen, Mosbacher, and  
Law Chair in Ophthalmology  
Cullen Eye Institute  
Baylor College of Medicine  
Houston, TX, USA

**Victor T.C. Koh, MBBS, MMed(Oph), FAMS**  
Associate Consultant, Ophthalmology  
National University Hospital  
Singapore

**Thomas Kohnen, MD, PhD, FEBO**  
Professor and Director  
Department of Ophthalmology  
University Clinic Frankfurt  
Goethe University  
Frankfurt am Main  
Germany

**Andrew Koustenis, BS**  
Medical Student  
Clinical Ophthalmology Research  
Internship  
Department of Ophthalmology  
Eugene and Marilyn Glick Eye Institute  
Indiana University  
School of Medicine  
Indianapolis, IN, USA

**Stephen S. Lane, MD**  
Medical Director  
Adjunct Clinical Professor  
Chief Medical Officer and Head Global  
Franchise Clinical Strategy  
Associated Eye Care  
University of Minnesota, Alcon  
Minneapolis, MN, USA

**Patrick J.M. Lavin, MB, MRCPI**  
Prof. Neurology and Ophthalmology  
Neurology, Ophthalmology and Visual  
Science  
Vanderbilt University Medical Center  
Nashville, TN, USA

**Fabio Lavinsky, MD, PhD, MBA**  
Research Fellow  
NYU Langone Eye Center  
NYU School of Medicine  
New York, NY, USA  
Director, Ophthalmic Imaging  
Department  
Lavinsky Eye Institute  
Porto Alegre, Brazil

**Andrew W. Lawton, MD**  
Director, Neuro-Ophthalmology  
Division  
Ochsner Health Services  
New Orleans, LA, USA

**Bryan S. Lee, MD, JD**  
Private Practitioner  
Altos Eye Physicians  
Los Altos, CA, USA  
Adjunct Clinical Assistant Professor of  
Ophthalmology  
Stanford University  
Stanford, CA, USA

**Daniel Lee, MD**  
Clinical Instructor, Glaucoma Service  
Wills Eye Hospital  
Philadelphia, PA, USA

**Gregory D. Lee, MD**  
Assistant Professor, Ophthalmology/  
Retina  
New York University  
New York, NY, USA

**Olivia L. Lee, MD**  
Assistant Professor of Ophthalmology  
David Geffen School of Medicine  
University of California Los Angeles  
Los Angeles, CA, USA  
Associate Medical Director  
Doheny Image Reading Center  
Doheny Eye Institute  
Los Angeles, CA, USA

**Paul P. Lee, MD, JD**

F. Bruce Fralick Professor and Chair  
Director W.K. Kellogg Eye Center  
Department of Ophthalmology &  
Visual Sciences  
University of Michigan  
Ann Arbor, MI, USA

**Richard M.H. Lee, MSc, FRCOphth**

Clinical Fellow  
Department of Glaucoma  
Moorfields Eye Hospital  
London, UK

**Dawn K.A. Lim, MBBS, MRCP,  
MMed(Int, Med), MMed(Ophth), FAMS**  
Consultant, Ophthalmology/Glaucoma  
National University Hospital  
Singapore

**Jennifer I. Lim, MD, FARVO**

Marion H. Schenk Esq. Chair in  
Ophthalmology for Research of the  
Aging Eye  
Professor of Ophthalmology  
Director of the Retina Service  
University of Illinois at Chicago  
Illinois Eye and Ear Infirmary  
Chicago, IL, USA

**Ridia Lim, MBBS, MPH, FRANZCO**

Ophthalmic Surgeon  
Glaucoma Service  
Sydney Eye Hospital  
Sydney, NSW, Australia

**Tony K.Y. Lin, MD, FRCSC**

Assistant Professor  
Department of Ophthalmology  
Schulich School of Medicine and  
Dentistry  
Western University  
London, ON, Canada

**John T. Lind, MD, MS**

Associate Professor  
Department of Ophthalmology &  
Visual Sciences  
Washington University in St Louis  
St Louis, MO, USA

**Yao Liu, MD**

Assistant Professor  
Department of Ophthalmology &  
Visual Sciences  
University of Wisconsin-Madison  
Madison, WI, USA

**Sidath E. Liyanage, MBBS, FRCOphth, PhD**

Consultant Ophthalmologist  
Bristol Eye Hospital  
Bristol, UK

**Alastair J. Lockwood, BM, BCh, FRCOphth, PhD**

Consultant, Ophthalmology  
Queen Alexandra Hospital  
Portsmouth, Hampshire, UK

**Nils A. Loewen, MD, PhD**

Associate Professor of Ophthalmology  
Vice Chair of Electronic Health  
Records in Ophthalmology  
University of Pittsburgh  
Pittsburgh, PA, USA

**Reid A. Longmuir, MD**

Assistant Professor  
Department of Ophthalmology &  
Visual Sciences  
Vanderbilt University  
Nashville, TN, USA

**Pedro F. Lopez, MD**

Professor and Founding Chair  
Department of Ophthalmology  
Herbert Wertheim College of Medicine  
Florida International University  
Director of Vitreoretina and Macular  
Division  
Center for Excellence in Eye Care  
Miami, FL, USA

**Mats Lundström, MD, PhD**

Adjunct Professor Emeritus  
Department of Clinical Sciences,  
Ophthalmology  
Faculty of Medicine  
Lund University  
Lund, Region Skåne, Sweden

**Robi N. Maamari, MD**

Ophthalmology Resident  
Department of Ophthalmology &  
Visual Sciences  
Washington University School of  
Medicine in St Louis  
St Louis, MO, USA

**Assumpta Madu, MD, MBA, PharmD**

Vice Chair, Operations  
Associate Clinical Professor of  
Ophthalmology  
NYU School of Medicine  
NYU Langone Medical Center  
New York, NY, USA

**Maya H. Maloney, MD**

Consultant, Medical Retina  
Mayo Clinic  
Rochester, MN, USA

**Naresh Mandava, MD**

Professor and Chair  
Department of Ophthalmology  
University of Colorado  
School of Medicine  
Denver, CO, USA

**Michael F. Marmor, MD**

Professor  
Department of Ophthalmology  
Byers Eye Institute  
Stanford University  
School of Medicine  
Palo Alto, CA, USA

**Jeevan R. Mathura, Jr., MD**

Private Practitioner and Owner  
Diabetic Eye and Macular Disease  
Specialists, LLC  
Washington, DC, USA

**Cynthia Mattox, MD**

Associate Professor, Ophthalmology  
Tufts University  
School of Medicine  
Boston, MA, USA

**Scott K. McClatchey, MD**

Associate Professor, Ophthalmology  
Naval Medical Center  
San Diego, CA, USA

**Stephen D. McLeod, MD**

Theresa M. and Wayne M. Caygill  
Distinguished Professor and Chair,  
Ophthalmology  
University of California San Francisco  
San Francisco, CA, USA

**Brian D. McMillan, MD**

Assistant Professor of Ophthalmology  
WVU Eye Institute  
West Virginia University  
School of Medicine  
Morgantown, WV, USA

**Alan A. McNab, DMedSc, FRANZCO, FRCOphth**

Associate Professor and Director  
Orbital Plastic and Lacrimal Clinic  
Royal Victorian Eye and Ear Hospital  
Melbourne, VIC, Australia

**Jodhbir S. Mehta, BSc, MD, MBBS, FRCS(Ed), FRCOphth, FAMS**

Associate Professor, Cornea and  
External Disease  
Singapore National Eye Centre  
Singapore

**Luis J. Mejico, MD**

Professor and Chair of Neurology  
Professor of Ophthalmology  
SUNY Upstate Medical University  
Syracuse, NY, USA

**Carolina L. Mercado, MD**

Clinical Research Fellow,  
Ophthalmology  
Bascom Palmer Eye Institute  
Miami, FL, USA

**Shahzad I. Mian, MD**

Associate Chair, Terry J. Bergstrom  
Professor  
Associate Professor, Ophthalmology &  
Visual Sciences  
University of Michigan  
Ann Arbor, MI, USA

**William F. Mieler, MD, FACS**

Cless Family Professor of  
Ophthalmology  
Vice-Chairman of Education  
Illinois Eye and Ear Infirmary  
University of Illinois at Chicago  
College of Medicine  
Chicago, IL, USA

**David Miller, MD**

Associate Clinical Professor of  
Ophthalmology  
Harvard Medical School  
Boston, MA, USA

**Kyle E. Miller, MD**

Assistant Professor, Ophthalmology  
Naval Medical Center Portsmouth  
Portsmouth, VA, USA

**Tatsuya Mimura, MD, PhD**

Tokyo Womens Medical University  
Medical Center East  
Tokyo, Japan

**Rukhsana G. Mirza, MD**

Associate Professor  
Department of Ophthalmology  
Northwestern University  
Feinberg School of Medicine  
Chicago, IL, USA

**Mihai Mititelu, MD, MPH**

Assistant Professor  
Department of Ophthalmology &  
Visual Sciences  
University of Wisconsin-Madison  
School of Medicine and Public Health  
Madison, WI, USA

**Ramana S. Moorthy, MD**

Clinical Associate Professor,  
Ophthalmology  
Indiana University  
School of Medicine  
Founding Partner and CEO  
Associated Vitreoretinal and Uveitis  
Consultants  
Indianapolis, IN, USA

**Andrew A. Moshfeghi, MD, MBA**

Director, Vitreoretinal Fellowship  
Associate Professor of Clinical  
Ophthalmology  
University of Southern California  
Roski Eye Institute  
Keck School of Medicine  
Los Angeles, CA, USA

**Majid Moshirfar, MD, FACS**

Professor of Ophthalmology  
Hoopes Vision and John A. Moran Eye  
Center  
Draper, UT, USA

**Heather E. Moss, MD, PhD**

Assistant Professor  
Departments of Ophthalmology and  
Neurology & Neurological Sciences  
Stanford University  
Palo Alto, CA, USA

**Mark L. Moster, MD**

Director, Neuro-Ophthalmology  
Fellowship  
Professor, Neurology and  
Ophthalmology  
Wills Eye Hospital  
Sidney Kimmel Medical College of  
Thomas Jefferson University  
Philadelphia, PA, USA

**Kelly W. Muir, MD, MHSc**

Associate Professor of Ophthalmology,  
Glaucoma Division  
Duke University  
School of Medicine  
Durham, NC, USA

**Ann G. Neff, MD**

Dermatology Associates  
Sarasota, FL, USA

**Jeffrey A. Nerad, MD**

Oculoplastic & Reconstructive Surgery  
Cincinnati Eye Institute  
Volunteer Professor, Ophthalmology  
University of Cincinnati  
Cincinnati, OH, USA

**Neda Nikpoor, MD**

Clinical Instructor, Ophthalmology  
Byers Eye Institute  
Stanford University  
Palo Alto, CA, USA

**Robert J. Noecker, MD, MBA**

Director of Glaucoma  
Ophthalmic Consultants of  
Connecticut  
Fairfield, CT, USA

**Ricardo Nosé, MD**

Clinical Research Fellow  
New England Eye Center  
Tufts Medical Center  
Boston, MA, USA

**Annabelle A. Okada, MD, DMSc**

Professor of Ophthalmology  
Kyorin University  
School of Medicine  
Tokyo, Japan

**Michael O'Keefe, FRCS**

Professor, Ophthalmology  
Mater Private Hospital  
Dublin, Ireland

**Jeffrey L. Olson, MD**

Associate Professor  
Department of Ophthalmology  
University of Colorado  
School of Medicine  
Denver, CO, USA

**Jane M. Olver, MB, BS, BSc, FRCS, FRCOphth**

Consultant Ophthalmologist  
Eye Department  
Clinica London  
London, UK

**Yvonne A.V. Opalinski, BSc, MD, BFA, MFA**

Clinical Associate Cardiovascular  
Surgery  
Department of Cardiovascular Surgery  
Trillium Health Partners  
Toronto, ON, Canada

**Faruk H. Öрге, MD**  
William R. and Margaret E. Althans  
Chair and Professor  
Director, Center for Pediatric  
Ophthalmology and Adult  
Strabismus  
Rainbow Babies, Children’s Hospital,  
UH Eye Institute  
Cleveland Medical Center  
Cleveland, OH, USA

**Mark Packer, MD, FACS, CPI**  
President  
Mark Packer MD Consulting, Inc.  
Boulder, CO, USA

**Suresh K. Pandey, MD**  
Director, Ophthalmology  
SuVi Eye Institute and Lasik Laser  
Center  
Kota, Rajasthan, India  
Visiting Assistant Professor  
John A. Moran Eye Center  
University of Utah  
Salt Lake City, UT, USA

**Vishal S. Parikh, MD**  
Vitreoretinal Surgery Fellow, Retina  
Service  
The Retina Institute  
St Louis, MO, USA

**Louis R. Pasquale, MD, FARVO**  
Professor of Ophthalmology  
Harvard Medical School  
Boston, MA, USA

**Sarju S. Patel, MD, MPH, MSc**  
Director of Uveitis  
Department of Ophthalmology  
Weill Cornell College of Medicine  
New York City, NY, USA

**Vivek R. Patel, MD**  
Associate Professor, Ophthalmology  
USC Roski Eye Institute  
Keck School of Medicine  
Los Angeles, CA, USA

**Carlos E. Pavesio, MD**  
Consultant Ophthalmic Surgeon  
Medical Retina  
Moorfields Eye Hospital  
London, UK

**Victor L. Perez, MD**  
Professor of Ophthalmology  
Stephen and Frances Foster Professor  
of Ophthalmology  
Duke University School of Medicine  
Director, Duke Center for Ocular  
Immunology  
Durham, NC, USA

**Claudia E. Perez-Straziota, MD**  
Clinical Assistant Professor of  
Ophthalmology  
Roski Eye Institute  
University of Southern California  
Private Practitioner  
Los Angeles, CA, USA

**Lauren T. Phillips, MD**  
Assistant Professor, Neurology &  
Neurotherapeutics  
University of Texas  
Southwestern Medical Center  
Dallas, TX, USA

# Acknowledgments

We are grateful to the editors and authors who have contributed to *Ophthalmology* and to the superb, dedicated *Ophthalmology* team at Elsevier. We especially would like to thank Sharon Nash and Russell Gabbedy for their tireless efforts in keeping us on track and making our job much easier. We would also like to thank Josh Mearns, Content Coordinator; Joanna Souch, Project Manager; Brian Salisbury, Designer; Karen Giacomucci, Illustration Manager; Richard Tibbitts, Illustrator; Vinod Kothaparamtath, Multimedia Producer; and Claire McKenzie, Marketing Manager.

# Dedication

We would like to dedicate this book to our wives, Karin Yanoff and Julie Starr-Duker, and to our children—Steven, David, and Alexis Leyva-Yanoff; Joanne Grune-Yanoff; and Jake, Claire, Bear, Becca, Sam, Colette, and Elly Duker—all of whom play such an important part in our lives and without whose help and understanding we would have never come this far.

# Fundamentals of Human Genetics

Janey L. Wiggs

## 1.1

**Definition:** The central principles of human genetics with relevance to eye disease.

### Key Features

- Gene structure and expression.
- Organization and inheritance of the human genome.
- Mutations and clinical phenotypes.
- Gene-based therapies.

## DNA AND THE CENTRAL DOGMA OF HUMAN GENETICS

The regulation of cellular growth and function in all human tissue is dependent on the activities of specific protein molecules. In turn, protein activity is dependent on the expression of the genes that contain the correct DNA sequence for protein synthesis. The DNA molecule is a double-stranded helix. Each strand is composed of a sequence of four nucleotide bases—adenine (A), guanine (G), cytosine (C), and thymine (T)—joined to a sugar and a phosphate. The order of the bases in the DNA sequence forms the genetic code that directs the expression of genes. The double-stranded helix is formed as a result of hydrogen bonding between the nucleotide bases of opposite strands.<sup>1</sup> The bonding is specific, such that A always pairs with T, and G always pairs with C. The specificity of the hydrogen bonding is the molecular basis of the accurate copying of the DNA sequence that is required during the processes of DNA replication (necessary for cell division) and transcription of DNA into RNA (necessary for gene expression and protein synthesis; Fig. 1.1.1).

Gene expression begins with the recognition of a particular DNA sequence called the promoter sequence as the start site for RNA synthesis by the enzyme RNA polymerase. The RNA polymerase “reads” the DNA sequence and assembles a strand of RNA that is complementary to the DNA sequence. RNA is a single-stranded nucleic acid composed of the same nucleotide bases as DNA, except that uracil takes the place of thymine. Human genes (and genes found in other eukaryotic organisms) contain many DNA sequences that are not translated into polypeptides and proteins. These sequences are called intervening sequences or introns. Introns do not have any known specific function, and although they are transcribed into RNA by RNA polymerase, they are spliced out of the initial RNA product (termed heteronuclear RNA, or hnRNA) to form the completed messenger RNA (mRNA). Untranslated RNA may have specific functions. For example, antisense RNA and micro RNAs (miRNA) appear to regulate expression of genes.<sup>2</sup> The mRNA is the template for protein synthesis. Proteins consist of one or more polypeptide chains, which are sequences of specific amino acids. The sequence of bases in the mRNA directs the order of amino acids that make up the polypeptide chain. Individual amino acids are encoded by units of three mRNA bases, termed codons. Transfer RNA (tRNA) molecules bind specific amino acids and recognize the corresponding three-base codon in the mRNA. Cellular organelles called ribosomes bind the mRNA in such a configuration that the RNA sequence is accessible to tRNA molecules and the amino acids are aligned to form the polypeptide. The polypeptide chain may be processed by a number of other chemical reactions to form the mature protein (Fig. 1.1.2).

## HUMAN GENOME

Human DNA is packaged as chromosomes located in the nuclei of cells. Chromosomes are composed of individual strands of DNA wound about proteins called histones. The complex winding and coiling process culminates in the formation of a chromosome. The entire collection of human chromosomes includes 22 paired autosomes and two sex chromosomes. Women have two copies of the X chromosome, and men have one X and one Y chromosome (Fig. 1.1.3).

The set consisting of one of each autosome as well as both sex chromosomes is called the *human genome*. The chromosomal molecules of DNA from one human genome, if arranged in tandem end to end, contain approximately 3.2 billion base pairs (bp). The Human Genome Project was formally begun in 1990 with the defined goals to: identify all the approximately 20,000–25,000 genes in human DNA; determine the sequences of the 3 billion chemical base pairs that make up human DNA; store this information in publicly available databases; improve tools for data analysis; transfer related technologies to the private sector; and address the

**Fig. 1.1.1 Structure of the DNA Double Helix.** The sugar-phosphate backbone and nitrogenous bases of each individual strand are arranged as shown. The two strands of DNA pair by hydrogen bonding between the appropriate bases to form the double-helical structure. Separation of individual strands of the DNA molecule allows DNA replication, catalyzed by DNA polymerase. As the new complementary strands of DNA are synthesized, hydrogen bonds are formed between the appropriate nitrogenous bases.

**Fig. 1.12 The Central Dogma of Molecular Genetics.** Transcription of DNA into RNA occurs in the nucleus of the cell, catalyzed by the enzyme RNA polymerase. Mature mRNA is transported to the cytoplasm, where translation of the code produces amino acids linked to form a polypeptide chain, and ultimately a mature protein is produced.

ethical, legal, and social issues that may arise from the project. One of the most important goals, the complete sequence of the human genome, was completed in draft form in 2001.<sup>3</sup> Catalogs of variation in the human genome sequence have also been completed, with the microsatellite repeat map in 1994,<sup>4</sup> the release of the HapMap from the International HapMap Consortium in 2004,<sup>5</sup> and more recently a catalog of variants from the 1000 genomes project.<sup>6</sup> dbSNP (<https://www.ncbi.nlm.nih.gov/projects/SNP/>) is a database listing single nucleotide polymorphisms (SNPs) that are single-letter variations in a DNA base sequence. SNPs are bound together to form haplotypes, which are blocks of SNPs that are commonly inherited together. This binding occurs through the phenomenon of linkage disequilibrium. Within a haplotype block, which may extend for 10,000–100,000 bases of DNA, the analysis of only a subset of all SNPs may “tag” the entire haplotype. The International HapMap project has performed an initial characterization of the linkage disequilibrium patterns between SNPs in multiple different populations. The SNP haplotype blocks identified can be examined for association with human disease, especially common disorders with complex inheritance. Knowledge about the effects of DNA variations among individuals can lead to new ways to diagnose, treat, and prevent human disease. This approach has been used successfully to identify the risk loci for age-related macular degeneration,<sup>7–9</sup> myopia,<sup>10,11</sup> primary open-angle glaucoma,<sup>12–14</sup> and Fuchs’ endothelial dystrophy.<sup>15</sup>

## Mitosis and Meiosis

In order for cells to divide, the entire DNA sequence must be copied so that each daughter cell can receive a complete complement of DNA. The growth phase of the cell cycle terminates with the separation of the two sister chromatids of each chromosome, and the cell divides during mitosis. Before cell division, the complete DNA sequence is copied by the enzyme DNA polymerase in a process called DNA replication. DNA polymerase is an enzyme capable of the synthesis of new strands of DNA using the exact sequence of the original DNA as a template. Once the DNA is copied, the old and new copies of the chromosomes form their respective pairs, and the cell divides such that one copy of each chromosome pair belongs to each cell (Fig. 1.14). Mitotic cell division produces a daughter cell that is an exact replica of the dividing cell.

Meiotic cell division is a special type of cell division that results in a reduction of the genetic material in the daughter cells, which become the reproductive cells—eggs (women) and sperm (men). Meiosis begins with DNA replication, followed by a pairing of the maternal and paternal chromosomes (homologous pairing) and an exchange of genetic material

## PACKAGING OF DNA INTO CHROMOSOMES

**Fig. 1.13 The Packaging of DNA Into Chromosomes.** Strands of DNA are wound tightly around proteins called histones. The DNA–histone complex becomes further coiled to form a nucleosome, which in turn coils to form a solenoid. Solenoids then form complexes with additional proteins to become the chromatin that ultimately forms the chromosome.

between chromosomes by recombination (Fig. 1.15). The homologous chromosome pairs line up on the microtubule spindle and divide such that the maternal and paternal copies of the doubled chromosomes are distributed to separate daughter cells. A second cell division occurs, and the doubled chromosomes divide, which results in daughter cells that have half the genetic material of somatic (tissue) cells.

## BASIC MENDELIAN PRINCIPLES

Two important rules central to human genetics emerged from the work of Gregor Mendel, a nineteenth century Austrian monk. The first is the principle of segregation, which states that genes exist in pairs and that only one member of each pair is transmitted to the offspring of a mating couple. The principle of segregation describes the behavior of chromosomes in meiosis. Mendel’s second rule is the law of independent assortment, which states that genes at different loci are transmitted independently. This work also demonstrated the concepts of dominant and recessive traits. Mendel found that certain traits were dominant and could mask the presence of a recessive gene.

At the same time that Mendel observed that most traits segregate independently, according to the law of independent assortment, he unexpectedly found that some traits frequently segregate together. The physical arrangement of genes in a linear array along a chromosome is the

**Fig. 1.1.4 The Mitotic Cell Cycle.** During mitosis, the DNA of a diploid cell is replicated, which results in the formation of a tetraploid cell that divides to form two identical diploid daughter cells.

explanation for this surprising observation. On average, a recombination event occurs once or twice between two paired homologous chromosomes during meiosis (Fig. 1.1.6). Most observable traits, by chance, are located far away from one another on a chromosome, such that recombination is likely to occur between them, or they are located on entirely different chromosomes. If two traits are on separate chromosomes, or a recombination event is likely to occur between them on the same chromosome, the resultant gamete formed during meiosis has a 50% chance of inheriting different alleles from each loci, and the two traits respect the law of independent assortment. If, however, the loci for these two traits are close together on a chromosome, with the result that a recombination event occurs between them only rarely, the alleles at each loci are passed to descendent gametes “in phase.” This means that the particular alleles present at each loci in the offspring reflect the orientation in the parent, and the traits appear to be “linked.” For example, in Mendel’s study of pea plants, curly leaves were always found with pink flowers, even though the genes for curly leaves and pink flowers are located at distinct loci. These traits are linked, because the curly leaf gene and the pink-flower gene are located close to each other on a chromosome, and a recombination event only rarely occurs between them. Recombination and linkage are the fundamental concepts behind genetic linkage analysis.

## MUTATIONS

Mutations are changes in the gene DNA sequence that result in a biologically significant change in the function of the encoded protein. If a

**Fig. 1.1.5 The Meiotic Cell Cycle.** During meiosis, the DNA of a diploid cell is replicated, which results in the formation of a tetraploid cell that divides twice to form four haploid cells (gametes). As a consequence of the crossing over and recombination events that occur during the pairing of homologous chromosomes before the first division, the four haploid cells may contain different segments of the original parental chromosomes. For brevity, prophase II and telophase II are not shown.

**Fig. 1.1.6 Genetic Recombination by Crossing Over.** Two copies of a chromosome are copied by DNA replication. During meiosis, pairing of homologous chromosomes occurs, which enables a crossover between chromosomes to take place. During cell division, the recombined chromosomes separate into individual daughter cells.

particular gene is mutated, the protein product might not be produced, or it might be produced but function poorly or even pathologically (dominant negative effect). *Point mutations* (the substitution of a single base pair) are the most common mutations encountered in human genetics. *Missense mutations* are point mutations that cause a change in the amino

**Fig. 1.1.7 Reciprocal Translocation Between Two Chromosomes.** The Philadelphia chromosome (responsible for chronic myelogenous leukemia) is shown as an example of a reciprocal chromosomal translocation that results in an abnormal gene product responsible for a clinical disorder. In this case an exchange occurs between the long arm of chromosome 9 and the long arm of chromosome 22.

acid sequence of the polypeptide chain. The severity of the missense mutation is dependent on the chemical properties of the switched amino acids and on the importance of a particular amino acid in the function of the mature protein. Point mutations also may decrease the level of polypeptide production because they interrupt the promoter sequence, splice site sequences, or create a premature stop codon.

Gene expression can be affected by the insertion or deletion of large blocks of DNA sequence. These types of mutations are less common than point mutations but may result in a more severe change in the activity of the protein product. A specific category of *insertion mutations* is the expansion of trinucleotide repeats found in patients affected by certain neurodegenerative disorders. An interesting clinical phenomenon, “anticipation,” was understood on a molecular level with the discovery of trinucleotide repeats as the cause of myotonic dystrophy.<sup>16</sup> Frequently, offspring with myotonic dystrophy were affected more severely and at an earlier age than their affected parents and grandparents. Examination of the disease-causing trinucleotide repeat in affected pedigrees demonstrated that the severity of the disease correlated with the number of repeats found in the myotonic dystrophy gene in affected individuals. This phenomenon has been observed in a number of other diseases, including Huntington’s disease.<sup>17</sup>

*Chromosomal rearrangements* may result in breaks in specific genes that cause an interruption in the DNA sequence. Usually, the break in DNA sequence results in a truncated, unstable, dysfunctional protein product. Occasionally, the broken gene fuses with another gene to cause a “fusion polypeptide product,” which may have a novel activity in the cell. Often, such a novel activity results in an abnormality in the function of the cell. An example of such a fusion protein is the product of the chromosome 9;22 translocation that is associated with many cases of leukemia (Fig. 1.1.7).<sup>18,19</sup>

A set consisting of one of each autosome as well as an X or a Y chromosome is called a haploid set of chromosomes. The normal complement of two copies of each gene (or two copies of each chromosome) is called diploidy. Rarely, as a result of abnormal chromosome separation during cell division, a cell or organism may have three copies of each chromosome, which is called *triploidy*. A triploid human is not viable, but some patients have an extra chromosome or an extra segment of a chromosome. In such a situation, the abnormality is called *trisomy* for the chromosome involved. For example, patients with Down syndrome have three copies of chromosome 21, also referred to as trisomy 21.<sup>20</sup>

If one copy of a pair of chromosomes is absent, the defect is called *haploidy*. Deletions of the X chromosome are frequently the cause of Duchenne’s muscular dystrophy.<sup>21</sup>

*Polymorphisms* are changes in DNA sequence that don’t have a significant biological effect. These DNA sequence variants may modify disease processes, but alone are not sufficient to cause disease. Human DNA sequence is highly variable and includes single nucleotide polymorphisms (SNPs), microsatellite repeat polymorphisms (20–50 bp repeats of CA or GT sequence), variable number of tandem repeat polymorphisms (VNTR, repeats of 50–100 bp of DNA), or larger insertion deletions.<sup>22</sup>

## GENES AND PHENOTYPES

The relationship between genes and phenotypes is complex. More than one genetic defect can lead to the same clinical phenotype (genetic heterogeneity), and different phenotypes can result from the same genetic defect (variable expressivity). Retinitis pigmentosa is an excellent example of genetic heterogeneity, as it may be inherited as an X-linked, autosomal dominant, autosomal recessive, or digenic trait, and more than 200 causative genes have been identified.<sup>23</sup> Other ocular disorders that are genetically heterogeneous include congenital cataract, glaucoma, and age-related macular degeneration. Different genes may contribute to a common phenotype because they affect different steps in a common pathway. Understanding the role of each gene in the disease process can help define the cellular mechanisms that are responsible for the disease.

For many genes, a single mutation that alters a critical site in the protein results in an abnormal phenotype. For some diseases, the resulting phenotypes are remarkably similar regardless of the nature of the mutation. For example, a wide variety of mutations in *RB1* cause retinoblastoma. Other diseases, however, exhibit variable expressivity, in which an individual’s mutation may be responsible for severe disease, mild disease, or disease that is not clinically detectable (incomplete penetrance). There are many examples of ocular disease demonstrating variable expressivity, including Kjer’s autosomal dominant optic atrophy,<sup>24</sup> Axenfeld–Rieger syndrome,<sup>25</sup> and aniridia.<sup>26</sup>

Different mutations in the same gene can also result in different phenotypes (allelic heterogeneity). Allelic heterogeneity accounts for the different phenotypes of dominant corneal stromal dystrophies caused by mutations in the *TGFBI/BIGH3*.<sup>27</sup> The phenotypic expression of a mutation may depend on its location within a gene. Such variable expressivity based on the location of the mutation is exemplified by mutations in the *rds* gene, which may cause typical autosomal dominant retinitis pigmentosa or macular dystrophy depending on the position of the genetic defect.<sup>28</sup>

## PATTERNS OF HUMAN INHERITANCE

The most common patterns of human inheritance are autosomal dominant, autosomal recessive, X-linked recessive, and mitochondrial. Fig. 1.1.8 shows examples of these four inheritance patterns. Other inheritance patterns less commonly encountered in human disease include X-linked dominant, digenic inheritance (polygenic), pseudodominance, and imprinting. Fig. 1.1.9 defines the notation and symbols used in pedigree construction.

### Autosomal Dominant

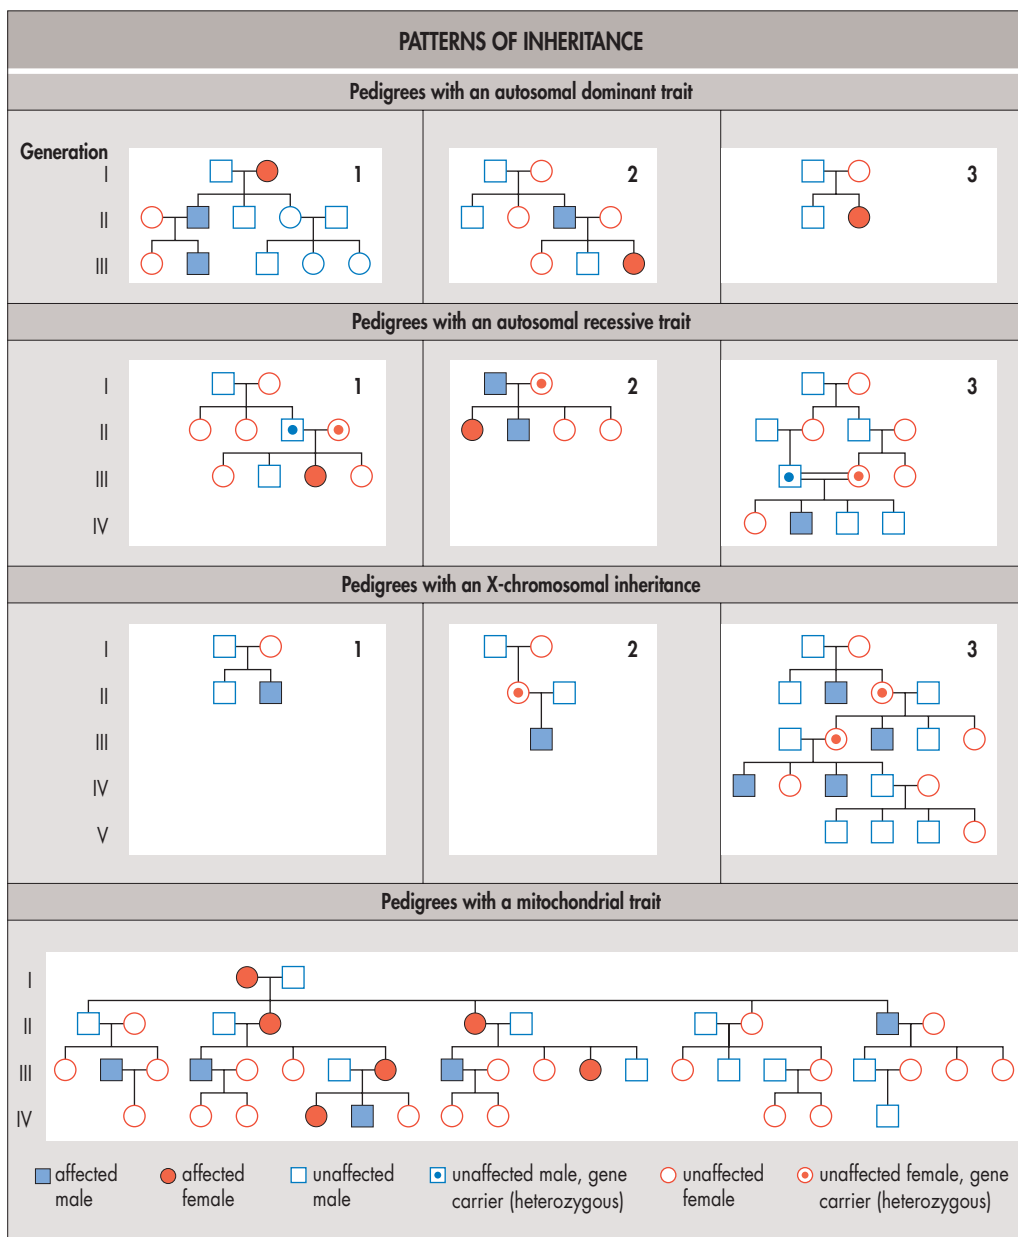

A disease-causing mutation that is present in only one of the two gene copies at an autosomal locus (heterozygous) is a dominant mutation. For example, a patient with dominant retinitis pigmentosa will have a defect in one copy of one retinitis pigmentosa gene inherited from one parent who, in most cases, is also affected by retinitis pigmentosa. The other copy of that gene, the one inherited from the unaffected parent, is normal (wild type). Affected individuals have a 50% chance of having affected siblings and a 50% chance of passing the abnormal gene to their offspring; 50% of children of an affected individual will be affected. For a dominant disease, males and females transmit the disease equally and are affected equally.

True dominant alleles produce the same phenotype in the heterozygous and homozygous states. In humans, most individuals affected by a disease caused by a dominant allele are heterozygous, but occasionally homozygous mutations have been described. In cases where the homozygous individual is more severely affected than the heterozygous individual, the disease is more appropriately noted to be inherited as a semidominant trait. For example, alleles in the *PAX3* gene, causing Waardenburg’s syndrome, are semidominant, because a homozygote with more severe disease compared with their heterozygote relatives has been described.<sup>29</sup>

In some pedigrees with an autosomal dominant disease, some individuals who carry the defective gene do not have the affected phenotype. However, these individuals can still transmit the disease gene to offspring and have affected children. This phenomenon is called reduced penetrance. The gene responsible for retinoblastoma (*RB1*) is only 90% penetrant, which means that 10% of the individuals who inherit a mutant copy of the gene do not develop the tumor.<sup>30</sup>

### Autosomal Recessive

Diseases that require both copies of a gene to be abnormal for development are inherited as recessive traits. Heterozygous carriers of mutant genes are

**Fig. 1.1.8 Patterns of Inheritance.** For pedigrees with an autosomal dominant trait, panel 1 shows inheritance that originates from a previous generation, panel 2 shows segregation that originates in the second generation of this pedigree, and panel 3 shows an apparent “sporadic” case, which is actually a new mutation that arises in the most recent generation. This mutation has a 50% chance of being passed to offspring of the affected individual. For pedigrees with an autosomal recessive trait, panel 1 shows an isolated affected individual in the most recent generation (whose parents are obligate carriers of the mutant gene responsible for the condition), panel 2 shows a pair of affected siblings whose father is also affected (for the siblings to be affected, the mother must be an obligate carrier of the mutant gene), and panel 3 shows an isolated affected individual in the most recent generation who is a product of a consanguineous marriage between two obligate carriers of the mutant gene. For pedigrees with an X-chromosomal trait, panel 1 shows an isolated affected individual whose disease is caused by a new mutation in the gene responsible for this condition, panel 2 shows an isolated individual who inherited a mutant copy of the gene from the mother (who is an obligate carrier), and panel 3 shows segregation of an X-linked trait through a multigeneration pedigree (50% of the male offspring are affected, and their mothers are obligate carriers of the disease). For pedigrees with a mitochondrial trait, the panel shows a large, multigeneration pedigree—men and women are affected, but only women have affected offspring.

usually clinically normal. The same recessive defect might affect both gene copies, in which case the patient is said to be a *homozygote*. Different recessive defects might affect the two gene copies, in which case the patient is a *compound heterozygote*. In a family with recessive disease, both parents are unaffected carriers, each having one wild-type gene (allele) and one mutant gene (allele). Each parent has a 50% chance of transmitting the defective allele to a child. Because a child must receive a defective allele from both parents to be affected, each child has a 25% chance of being affected ( $50\% \times 50\% = 25\%$ ), and 50% of the offspring will be carriers of the disease. If the parents are related, they may be carriers of the same rare mutations, and there is a greater chance that a recessive disease can be transmitted to offspring. Males and females have an equal chance of transmitting and inheriting the disease alleles.

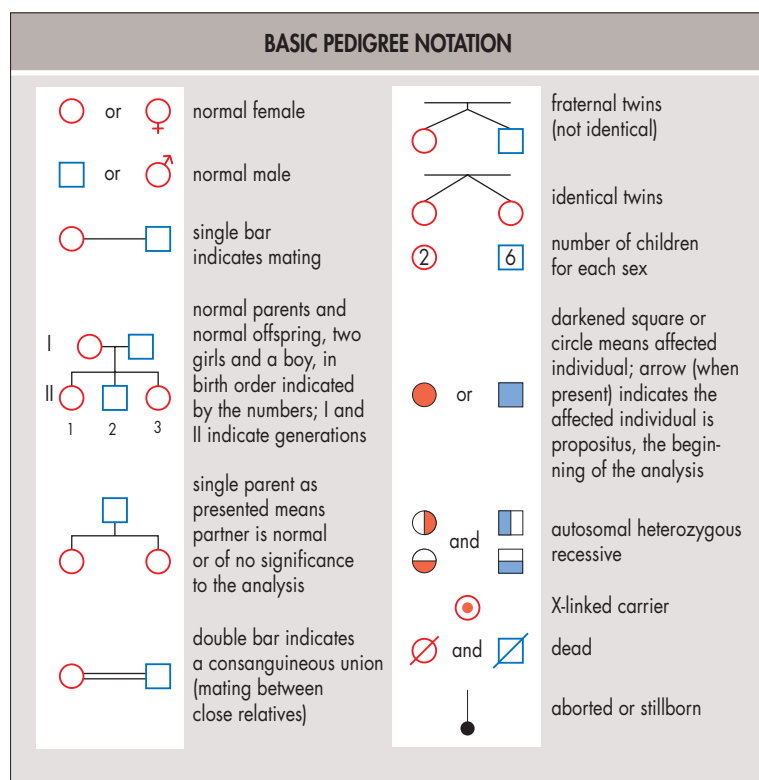

## X-Linked Recessive

Mutations of the X chromosome produce distinctive inheritance patterns, because males have only one copy of the X chromosome and females have two. Most X-linked gene defects are inherited as X-linked recessive traits. Carrier females are typically unaffected because they have both a normal copy and a defective copy of the disease-associated gene. Carrier males are affected because they only have one defective X chromosome and they do not have a normal gene copy to compensate for the defective copy. All of the daughters of an affected male will be carriers of the disease gene because they will inherit the defective X chromosome. None of the sons of an affected male will be affected or be carriers because they will inherit the Y chromosome. Each child of a carrier female has a 50% chance of inheriting the disease gene. If a son inherits the defective

gene, he will be affected. If a daughter inherits the defective gene, she will be a carrier. An important characteristic of X-linked recessive disorders is that males never transmit the disease to sons directly (male-to-male transmission).

Usually female carriers of an X-linked disease gene do not have any clinical evidence of the disease. However, for some X-linked diseases, mild clinical features can be found in female carriers. For example, in X-linked retinoschisis, affected males are severely affected, whereas carrier females have a visually insignificant but clinically detectable retinal abnormality.<sup>31</sup> Mild phenotypic expression of the disease gene can be caused by the process of *lyonization*. In order for males (with one X chromosome) and females (with two X chromosomes) to have equal levels of expression of X-linked genes, female cells express genes from only one of their two X chromosomes. The decision as to which X chromosome is expressed is made early in embryogenesis, and the line of descending cells faithfully adheres to the early choice. As a result, females are mosaics, with some cells in each tissue expressing the maternally derived X chromosome and the remainder expressing the paternally derived X chromosome. When one of the X chromosomes carries an abnormal gene, the proportion of cells that express the mutant versus the normal gene in each tissue can vary.

Females can also be affected by an X-linked recessive disease if the father is affected and the mother coincidentally is a carrier of a mutation in the disease gene. In this case, 50% of daughters would be affected, because 50% would inherit the X chromosome from the mother carrying the disease gene, and all the daughters would inherit the X chromosome from the father carrying the disease gene. Because most X-linked disorders are rare, the carrier frequency of disease genes in the general population is

**Fig. 1.1.9 Basic Pedigree Notation.** Typical symbols used in pedigree construction are defined.

low, and the chance that a carrier female would mate with a male affected by the same disease is quite low.

## Mitochondrial Inheritance

Mitochondria are small organelles located in the cytoplasm of cells. They function to generate ATP for the cell and are most abundant in cells that have high energy requirements, such as muscle and nerve cells. Mitochondria have their own small chromosome—16,569 bp of DNA encoding for 13 mitochondrial proteins, 2 ribosomal RNAs, and 22 tRNAs. Mutations occurring in genes located on the mitochondrial chromosome cause a number of diseases, including Leber's hereditary optic atrophy<sup>32</sup> and Kearns-Sayre syndrome.<sup>33</sup> Mutations occurring on the mitochondrial chromosome are inherited only from the mother because virtually all human mitochondria are derived from the maternal egg. Fathers do not transmit mitochondria to their offspring.

Cells vary in the number of mitochondria they contain, and when cells divide, the mitochondria are divided randomly. As a result, different cells can have varying numbers of mitochondria, and if a fraction of the mitochondria contain a mutated gene, different cells will have a varying proportion of healthy versus mutant mitochondria. The distribution of mutant mitochondria is called *heteroplasmy*, and the proportion of mutant mitochondria can vary from cell to cell and can also change with age. Differences in the relative proportions of mutant mitochondria can partly explain the observed variable severity of mitochondrial diseases and also the variable age of onset of mitochondrial diseases.

## Pseudodominance

This term describes an apparent dominant inheritance pattern due to recessive defects in a disease gene. This situation arises when a parent affected by a recessive disease (two abnormal copies of the disease gene) has a spouse who is a carrier of one abnormal copy of the disease gene. Children from this couple will always inherit a defective gene copy from the affected parent and will have a 50% chance of inheriting the defective gene copy from the unaffected carrier parent. On average, half of the children will inherit two defective gene copies and will be affected. The pedigree would mimic a dominant pedigree because of apparent direct transmission of the disease from the affected parent to affected children and because approximately 50% of the children will be affected. Pseudodominant transmission is uncommon, because few people are asymptomatic carriers for any particular recessive gene.

## X-Linked Dominant Inheritance

This inheritance pattern is similar to X-linked recessive inheritance, except that all females who are carriers of an abnormal gene on the X chromosome are affected rather than unaffected. All of the male offspring are also affected. Incontinentia pigmenti is probably inherited as an X-linked dominant trait. Affected females have irregularly pigmented atrophic scars on the trunk and the extremities and congenital avascularity in the peripheral retina with secondary retinal neovascularization.<sup>34</sup> This and other X-linked dominant disorders occur almost always in females, and it is likely that the X chromosome gene defects causing these diseases are embryonic lethals when present in males.

## Digenic Inheritance and Polygenic Inheritance

Digenic inheritance occurs when a patient has heterozygous defects in two different genes, and the combination of the two gene defects causes disease. Individuals who have a mutation in only one of the genes are normal. Digenic inheritance is different from recessive inheritance, because the two mutations involve different disease genes. In some retinitis pigmentosa families, mutation analysis of the peripherin gene and the *ROM1* gene showed that the affected individuals harbor specific mutations in both genes. Individuals with a mutation in only one copy of either gene were unaffected by the disease.<sup>35</sup> Triallelic inheritance has been described in some families affected by Bardet-Biedl syndrome (BBS). In these pedigrees, affected individuals carry three mutations in one or two BBS genes (12 BBS genes have been identified),<sup>36</sup> and unaffected individuals have only two abnormal alleles. In some families, it has been proposed that BBS may not be a single-gene recessive disease but a complex trait requiring at least three mutant alleles to manifest the phenotype. This would be an example of triallelic inheritance.<sup>37</sup>

If the expression of a heritable trait or predisposition is influenced by the combination of alleles at three or more loci, it is polygenic. Because of the complex inheritance, conditions caused by multiple alleles do not demonstrate a simple inheritance pattern. These complex traits may also be influenced by environmental conditions. Examples of phenotypes in ophthalmology that exhibit complex inheritance because of contributions of multiple genes and environmental factors are myopia,<sup>38</sup> age-related macular degeneration,<sup>39</sup> and adult-onset open-angle glaucoma.<sup>40</sup>

## Imprinting

Some mutations give rise to autosomal dominant traits that are transmitted by parents of either sex, but they are expressed only when inherited from a parent of one particular sex. In families affected with these disorders, they would appear to be transmitted in an autosomal dominant pattern from one parent (either the mother or the father) and would not be transmitted from the other parent. Occasionally, the same mutation gives rise to a different disorder depending on the sex of the parent transmitting the trait. These parental sex effects are evidence of a phenomenon called *imprinting*. Although the molecular mechanisms responsible for imprinting are not completely understood, it appears to be associated with DNA methylation patterns that can mark certain genes with their parental origin.<sup>41</sup>

## MOLECULAR MECHANISMS OF DISEASE

### Autosomal Dominant

Disorders inherited as autosomal dominant traits result from mutations that occur in only one copy of a gene (i.e., in heterozygous individuals). Usually, the parental origin of the mutation does not matter. However, if the gene is subject to imprinting, then mutations in the maternal or paternal copy of the gene may give rise to different phenotypes.

### Haploinsufficiency

Under normal circumstances, each copy of a gene produces a protein product. If a mutation occurs such that one copy of a gene no longer produces a protein product, then the amount of that protein in the cell has been reduced by half. Mutations that cause a reduction in the amount of protein or lead to inactivation of the protein are called *loss-of-function* mutations. For many cellular processes, this reduction in protein quantity does not have consequences, i.e., the heterozygous state is normal, and these mutations may be inherited as recessive traits (see later section). However, for some cellular processes there is an absolute requirement for the full dosage of protein product, which can only be furnished if both copies of

a particular gene are active. Diseases that are caused by inheritance of a single mutation reducing the protein level by half are inherited as dominant traits.

### Gain-of-Function Dominant Negative Effect

Autosomal dominant disorders can be caused by mutant proteins that have a detrimental effect on the normal tissue. Mutations in one copy of a gene may produce a mutant protein that can accumulate as a toxic product or in some other way interfere with the normal function of the cell. The mutant protein may also interfere with the function of the normal protein expressed by the remaining normal copy of the gene, thus eliminating any normal protein activity. It is possible to have gain-of-function mutations that can also be dominant negative because the new function of the protein also interferes with the function of the remaining normal copy of the gene.

### Autosomal and X-Linked Recessive

Recessive disorders result from mutations present on both the maternal and paternal copies of a gene. Mutations responsible for recessive disease typically cause a loss of biological activity, either because they create a defective protein product that has little or no biological activity or because they interfere with the normal expression of the gene (regulatory mutations). Most individuals heterozygous for recessive disorders, both autosomal and X-linked, are clinically normal.

## GENE THERAPY

Mutations in the DNA sequence of a particular gene can result in a protein product that is not produced, works poorly, or has acquired a novel function that is detrimental to the cell. Gene-based therapies can involve delivery of a normal gene to disease tissue, replacing or augmenting protein activity with other proteins or small molecules, decreasing abnormal gene expression, or genome-editing techniques to repair the mutation. Therapeutic genes can be delivered to specific tissues using modified viruses as vectors<sup>42</sup> (Fig. 1.1.10). A successful example of this approach is the restoration of vision in a canine model of Leber's congenital amaurosis using a recombinant adeno-associated virus carrying the normal gene (*RPE65*).<sup>43</sup> Human trials using a similar approach also successfully restored vision in patients with *RPE65* mutations.<sup>44</sup>

Diseases caused by mutations that create a gene product that is destructive to the cell (dominant negative or gain of function mutations) need to be treated using a different approach. In these cases, genes or oligonucleotides—in particular antisense molecules—that can reduce expression of the mutated gene are introduced into the cell.<sup>45</sup> Gene editing using CRISPR/Cas9 (Fig. 1.1.11) is another potentially useful approach for gain of function or loss of function mutations.<sup>46</sup> Recent advances have produced highly potent in vivo gene therapy vectors for targeting retina.<sup>47</sup> In addition, new methods are emerging to introduce therapeutic genes into damaged tissue using nonviral mechanisms based on nanotechnology.<sup>48</sup>

**Fig. 1.1.10 Gene Therapy Using a Retrovirus Vector.** A therapeutic gene is engineered genetically into the retrovirus DNA and replaces most of the viral DNA sequences. The “recombinant virus” that carries the therapeutic gene is allowed to replicate in a special “packaging cell” that also contains normal virus that carries the genes required for viral replication. The replicated recombinant virus is allowed to infect the human diseased tissue, or “target cell.” The recombinant virus may invade the diseased tissue but cannot replicate or destroy the cell. The recombinant virus inserts copies of the normal therapeutic gene into the host genome and produces the normal protein product.

**Fig. 1.1.11 Gene Editing Using CRISPR/Cas9.** The CRISPR/Cas-DNA binding creates a double-stranded DNA break (DSB), which can be repaired through nonhomologous end joining (NHEJ) or homology directed repair (HDR) pathways. Here, the *Streptococcus pyogenes* Cas9 nuclease, with a “NGG” protospacer adjacent motif (PAM) sequence, has been directed to target the region containing the BEST1 c929T > C (Ile310Thr) mutation. The guide RNA is complementary to the non-PAM strand, and the DNA cut site is three nucleotides from the PAM sequence. Double strand DNA breaks typically undergo repair by NHEJ, which results in deletions and insertions of variable length. DNA nicks are generally repaired through HDR, where a donor template can be used to incorporate precise genomic modifications. (Adapted from Hung SS, McCaughey T, Swann O, et al. Genome engineering in ophthalmology: application of CRISPR/Cas to the treatment of eye disease. *Prog Retin Eye Res* 2016;53:1–20.)

# Molecular Genetics of Selected Ocular Disorders

Janey L. Wiggs

# 1.2

**Definition:** The molecular mechanisms underlying selected inherited eye disorders as defined by the responsible genetic mutations.

## Key Features

- Inherited disorders affecting the ocular anterior segment.
- Genetic defects causing abnormal ocular development.
- Inherited retinal degenerations.
- Retinoblastoma.
- Disorders involving the optic nerve and extraocular muscles.

## INTRODUCTION

Tremendous advances in the molecular genetics of human disease have been made in the past 20 years. Many genes responsible for inherited eye diseases have been isolated and characterized, and the chromosomal location of a number of additional genes has been determined. Identifying and characterizing genes responsible for human disease has led to DNA-based methods of diagnosis; novel therapeutic approaches, including gene therapy; and improved knowledge about the molecular events that underlie the disease processes. The disorders discussed in this chapter represent important examples of major advances in human ocular molecular genetics.

Although all inherited disorders are the result of gene mutations, the molecular consequences of a mutation are quite variable. The type of mutation responsible for a disease usually defines the inheritance pattern. For example, mutations that create an abnormal protein detrimental to the cell are typically autosomal dominant, because only one mutant gene is required to disrupt normal cell function. Mutations that result in proteins that have reduced biological activity (loss of function) may be inherited as autosomal dominant or autosomal recessive conditions, depending on the number of copies of normal genes (and the amount of normal protein) required. Disorders may be caused by mutations in mitochondrial DNA that result in a characteristic maternal inheritance pattern. Also, mutations in genes carried on the X chromosome result in characteristic inheritance patterns.

## DOMINANT CORNEAL DYSTROPHIES

The autosomal dominant corneal dystrophies are an excellent example of dominant negative mutations that result in the formation of a toxic protein. Four types of autosomal dominant dystrophies that affect the stroma of the cornea are well characterized<sup>1</sup>:

- Groenouw (granular) type I.
- Lattice type I.
- Avellino (combined granular-lattice).
- Reis-Bücklers.

Although all four corneal dystrophies affect the anterior stroma, the clinical and pathological features differ. The granular dystrophies typically form discrete, white, localized deposits that may obscure vision progressively. Histopathologically, these deposits stain bright red with Masson

trichrome and have been termed “hyalin.” In lattice dystrophy, branching amyloid deposits gradually opacify the visual axis. These deposits exhibit a characteristic birefringence under polarized light after staining with Congo red. Avellino dystrophy includes features of both granular and lattice dystrophies. Reis-Bücklers dystrophy appears to involve primarily Bowman’s layer and the superficial stroma.

All four dystrophies were mapped genetically to a common interval on chromosome 5q31, and mutations in a single gene, *TGFB1* (also known as *BIGH3*), located in this region were found in affected individuals.<sup>2</sup> The product of this gene, keratoepithelin, is probably an extracellular matrix protein that modulates cell adhesion. Four different missense mutations, which occur at two arginine codons in the gene, have been found (Fig. 1.2.1). Interestingly, mutations at one of these arginine codons cause lattice dystrophy type I or Avellino dystrophy, the two dystrophies characterized by amyloid deposits. Mutations at the other arginine codon appear to result in either granular dystrophy or Reis-Bücklers dystrophy. The mutation analysis of this gene demonstrates that different mutations within a single gene can result in different phenotypes.

The mutation that causes Avellino and lattice dystrophies abolishes a putative phosphorylation site, which probably is required for the normal structure of keratoepithelin. Destruction of this aspect of the protein structure leads to formation of the amyloid deposits that are responsible for opacification of the cornea. Consequently, the mutant protein is destructive to the normal tissue. Mutations at the R555 (arginine at amino acid position 555) appear to result in either granular dystrophy or Reis-Bücklers dystrophy. These phenotype-genotype correlations demonstrate the variable expressivity of mutations in this gene and the significance of alteration of the arginine residues 124 and 555.

## ANIRIDIA, PETER’S ANOMALY, AUTOSOMAL DOMINANT KERATITIS

Some cellular processes require a level of protein production that results from the expression of both copies of a particular gene. Such proteins may be involved in a variety of biological processes. Certain disorders are caused by the disruption of one copy of a gene that reduces the protein level by half. Such a reduction is also called “haploinsufficiency.”

**Fig. 1.2.1 Keratoepithelin Gene.** Arrows point to the location of the reported mutations.

**Fig. 1.2.2 The *PAX6* Gene.** (Data with permission from Glaser T, et al. *PAX6* gene mutations in aniridia. In: Wiggs JL, editor. *Molecular genetics of ocular disease*. New York: Wiley-Liss; 1995. p. 51–82.)

Mutations in the *PAX6* gene are responsible for aniridia, Peter's anomaly, and autosomal dominant keratitis.<sup>3</sup> Most of the mutations responsible for these disorders alter the paired-box sequence within the gene (Fig. 1.2.2) and result in inactivation of one copy of the *PAX6* gene. The paired-box sequence is an important element that is necessary for the regulatory function of the protein. Losing half the normal paired-box sequence, and probably other regulatory elements within the gene, appears to be the critical event that results in the associated ocular disorders. The protein plays an important role in ocular development, presumably by regulating the expression of genes that are involved in embryogenesis of the eye. A reduction in the amount of active gene product alters the expression of these genes, which results in abnormal development. The genes that code for the lens crystallin proteins are one class of genes developmentally regulated by the *PAX6* protein.

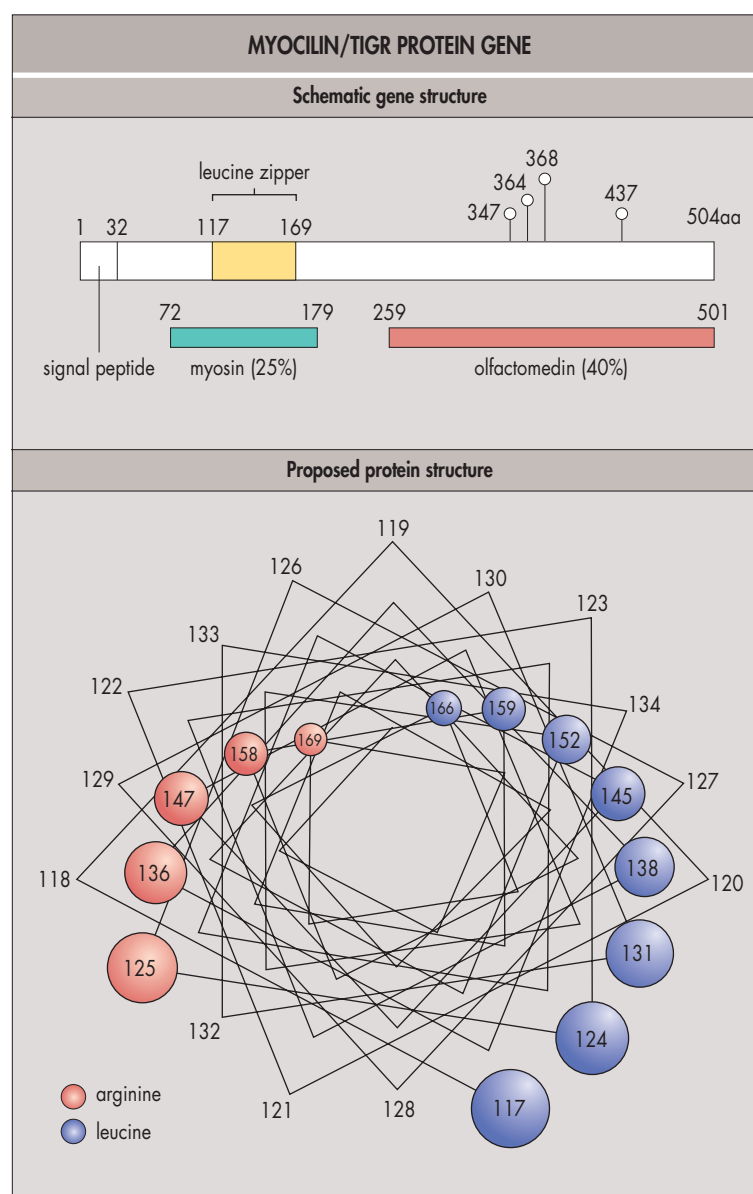

The clinical disorders caused by mutations in *PAX6* exhibit extensive phenotypic variability. Similar mutations may give rise to aniridia, Peter's anomaly, or autosomal dominant keratitis. Variation in the phenotype associated with a mutation is termed "variable expressivity" and is a common feature of disorders that arise from haploinsufficiency. It is possible that the variability of the mutant phenotype results from the random activation of downstream genes that occurs when only half the required gene product is available.

## RIEGER'S SYNDROME

Rieger's syndrome is an autosomal dominant disorder of morphogenesis that results in abnormal development of the anterior segment of the eye. Typical clinical findings may include posterior embryotoxon, iris hypoplasia, iridocorneal adhesions, and corectopia. Approximately 50% of affected individuals develop a high-pressure glaucoma associated with severe optic nerve disease. The cause of the glaucoma associated with this syndrome is not known, although anomalous development of the anterior chamber angle structures is usually found.

Genetic heterogeneity of Rieger's syndrome is indicated by the variety of chromosomal abnormalities that have been associated with the condition, including deletions of chromosome 4 and chromosome 13. Genes for Rieger's syndrome are located on chromosomes 4q25, 13q14, and 6p25. Iris hypoplasia is the dominant clinical feature of pedigrees linked to the 6p25 locus, whereas pedigrees linked to 4q25 and 13q14 demonstrate the full range of ocular and systemic abnormalities found in these patients.

The genes located on chromosomes 4q25 and 6p25 have been identified.<sup>4</sup> The chromosome 4q25 gene (*PITX2*) codes for a bicoid homeobox transcription factor. Like *PAX6*, this gene is expressed during eye development and is probably involved in the ocular developmental processes. The chromosome 6p25 gene *FOXC1* (also called *FKHL7*) is a member of a forkhead family of regulatory proteins. *FOXC1* is expressed during ocular development, and mutations alter the dosage of the gene product. There is some indication that the *FOXC1* protein and the *PITX2* protein interact during ocular development. The identification of other genes responsible for Rieger's syndrome and anterior segment dysgenesis is necessary to determine whether these genes are part of a common developmental pathway or represent redundant functions necessary for eye development.

**Fig. 1.2.3 *MYOC* (Myocilin).** The myosin-like domain, the olfactomedin-like domain, and the leucine zipper are indicated. Amino acids altered in patients with juvenile- or adult-onset glaucoma are shown. (Reprinted by permission of Federation of the European Biochemical Societies from Orteto J, Escibano J, Coca-Prados M. Cloning and characterization of subtracted cDNAs from a human ciliary body library encoding TIGR, a protein involved in juvenile open angle glaucoma with homology to myosin and olfactomedin. *FEBS Lett* 1997;413:349–53.)

## JUVENILE GLAUCOMA

Primary juvenile open-angle glaucoma is a rare disorder that develops during the first two decades of life. Affected patients typically present with a high intraocular pressure (IOP), which ultimately requires surgical therapy. Juvenile glaucoma may be inherited as an autosomal dominant trait, and large pedigrees have been identified and used for genetic linkage analysis. One gene responsible for this condition, *MYOC*, codes for the myocilin protein and is located on chromosome 1q23 (*GLC1A*).

Myocilin has been shown to be expressed in the human retina, ciliary body, and trabecular meshwork. The protein has several functional domains, including a region homologous to a family of proteins called olfactomedins. Although the function of the protein and the olfactomedin domain is not known, nearly all the mutations associated with glaucoma have been found in the olfactomedin portion of the protein (Fig. 1.2.3).<sup>5</sup> Mutations in myocilin also have been associated with some cases of adult-onset primary open-angle glaucoma. Patients with only one copy of the myocilin gene (because of chromosomal deletion removing the second copy of the gene) or without any functional myocilin (caused by homozygosity of a stop-codon polymorphism in the first part of the gene) do not develop glaucoma. Collectively these results suggest that mutations in myocilin cause a gain-of-function or dominant negative effect rather than a loss-of-function or haploinsufficiency. The role of myocilin in IOP

elevation is not completely known, but in vitro studies show that myocilin mutants are misfolded and detergent resistant. Myocilin mutations may be secretion incompetent and accumulate in the endoplasmic reticulum (ER) inducing ER stress. Recent studies using a transgenic mouse model indicate that compounds that relieve ER stress can also reduce the mutation-associated elevation of IOP.<sup>6</sup>

CONGENITAL GLAUCOMA

Congenital glaucoma is a genetically heterogeneous condition, with both autosomal recessive and autosomal dominant forms reported. Two genes responsible for autosomal recessive congenital glaucoma have been identified, *CYP11B1*, a member of the cytochrome P-450 family of proteins (cytochrome P-45011B1)<sup>7</sup> and *LTBP2* (latent transforming growth factor beta binding protein 2).<sup>8</sup> Mutations in *CYP11B1* have been identified in patients with autosomal recessive congenital glaucoma from all over the world but especially in areas where consanguinity is a custom.<sup>9</sup> Responsible mutations disrupt the function of the protein, implying that a loss of function of the protein results in the phenotype.<sup>9</sup> Recurrent mutations are likely to be the result of founder chromosomes that have been distributed to populations throughout the world.<sup>10,11</sup> Because the defects responsible for congenital glaucoma are predominantly developmental, cytochrome P-45011B1 and latent transforming growth factor beta binding protein 2 must play a direct or indirect role in the development of the anterior segment of the eye.

NONSyndromic Congenital Cataract

At least one-third of all congenital cataracts are familial and are not associated with other abnormalities of the eye or with systemic abnormalities. A number of different genes can contribute to congenital cataract, including some that code for the crystallin proteins.<sup>12</sup> The human  $\gamma$ -crystallin genes constitute a multigene family that contains at least seven highly related members. All seven of the  $\gamma$ -crystallin genes have been assigned to chromosome 2q34-q35. Of the genes mapped to this region, only two of them,  $\gamma$ -C and  $\gamma$ -D, encode abundant proteins. Two of the genes,  $\gamma$ -E and  $\gamma$ -F, are pseudogenes, which means they are not expressed in the normal lens. A pedigree affected by the Coppock cataract, a congenital cataract that involves primarily the embryonic lens, was shown to be linked genetically to the region that contains the  $\gamma$ -crystallin genes. In individuals affected by the Coppock cataract, additional regulatory sequences have been found in the promoter region of the  $\gamma$ -E pseudogene.<sup>13</sup> This result implies that the  $\gamma$ -E pseudogene is expressed in affected individuals and that expression of the pseudogene is the event that leads to cataract formation. A number of other genes have been associated with hereditary cataract. A useful collection of mutations and phenotypes can be found at the OMIM website (Table 1.2.1).

RETINITIS PIGMENTOSA

The molecular genetics of retinitis pigmentosa (RP) is exceedingly complex. The disease can exhibit sporadic, autosomal dominant, autosomal recessive, X-linked, or digenic inheritance. At least 200 genes are known to be associated with RP, and a number of genes have been mapped but not yet found. Most of these genes are expressed preferentially in the retina, but some are expressed systemically. A useful resource listing genes responsible for various forms of retinal diseases, including retinitis pigmentosa, can be found at the RetNet website (<http://www.sph.uth.tmc.edu/Retnet/>).

Mutations in rhodopsin can cause an autosomal dominant form of RP that provides an interesting example of how mutant proteins can interfere with normal cellular processes. Initially, one form of autosomal dominant RP was mapped to chromosome 3q24. With a candidate gene approach, the rhodopsin gene was identified as the cause of the disease in affected families.<sup>14</sup> Many of the first mutations detected in the rhodopsin protein were missense mutations located in the C-terminus of the gene (Fig. 1.2.4). To explore the pathogenical mechanisms of these mutations, transgenic mice were created that carried mutant copies of the gene.<sup>15</sup> Histopathological studies of these mice showed an accumulation of vesicles that contained rhodopsin at the junction between the inner and outer segments of the photoreceptors. The vesicles probably interfere with the normal regeneration of the photoreceptors, thus causing photoreceptor degeneration. Because the C-terminus of the nascent polypeptide is involved in the transport of the maturing protein, the accumulation of rhodopsin-filled vesicles is likely to result from abnormal transport of the mutant rhodopsin to the membranes of the outer segments.

Null mutations (mutations that cause a prematurely shortened or truncated protein) also have been found in the rhodopsin gene in patients who have autosomal recessive retinitis pigmentosa (see Fig. 1.2.4).<sup>16</sup> Mutations responsible for recessive disease typically cause a loss of biological activity,

Fig. 1.2.4 Human Rhodopsin Mutations. The red circles indicate the amino acids altered by mutations in the gene in patients who have autosomal dominant retinitis pigmentosa. The translational stop site that results from a nonsense mutation is indicated as a red circle in a patient who has autosomal recessive retinitis pigmentosa.

either because they create a defective protein product that has little or no biological activity or because they interfere with the normal expression of the gene (regulatory mutations). Most individuals heterozygous for autosomal recessive disorders are clinically normal. Unlike the missense mutations responsible for the dominant form of the disease, the null mutations in rhodopsin produce an inactive protein that is not destructive to the cell. Null mutations result in retinitis pigmentosa only when they are present in both copies of the gene. Mutations in just one copy of the gene (heterozygous individuals) do not have a clinically detectable phenotype.

## STARGARDT DISEASE

Stargardt disease is characterized by progressive bilateral atrophy of the macular retinal pigment epithelium (RPE) and neuroepithelium, with the frequent appearance of orange–yellow flecks distributed around the macula. The choroid is characteristically dark on fluorescein angiography in about 80% of cases. The disease results in a loss of central acuity that may have a juvenile to adult onset and is inherited as an autosomal recessive trait. Inactivation of both copies of the responsible gene is necessary to cause the disease. Mutations in a photoreceptor cell-specific ATP-binding transporter gene (*ABCA4* or *ABCR*) have been found in affected patients.<sup>17,18</sup> Most disease-related mutations are missense mutations in conserved amino acid positions. The retina-specific ABC transporter (*ABCA4*) responsible for Stargardt disease is a member of a family of transporter proteins and is expressed in rod photoreceptors, which indicates that this protein mediates the transport of an essential molecule either into or out of photoreceptor cells. Accumulation of a lipofuscin-like substance in *ABCA4*-related disease may result from inactivation of this transporter protein.

## X-LINKED JUVENILE RETINOSCHISIS

Retinoschisis is a maculopathy caused by intraretinal splitting; the defect most likely involves retinal Müller cells. Retinoschisis is inherited as an X-linked recessive trait. X-linked recessive disorders, like autosomal recessive disorders, are caused by inactivating mutations. Because men have only one X chromosome, one mutant copy of a gene responsible for an X-linked trait results in the disease. Usually women are heterozygous carriers of recessive X-linked traits and do not demonstrate any clinical abnormalities. Mutations in the gene coding for retinoschisin have been shown to be the cause of the disease.<sup>19</sup> The protein is involved in cell–cell interaction and may be active in cell adhesion processes during retinal development. Most retinoschisis gene (*XLR51*) mutations cause a loss of protein function.

## NORRIE'S DISEASE

Norrie's disease is an X-linked disorder characterized by progressive, bilateral, congenital blindness associated with retinal dysplasia that has been referred to as a “pseudoglioma.” The disease can include mental retardation and hearing defects. Norrie's disease is inherited as an X-linked recessive trait, and a causative gene has been identified on the X chromosome that has a tertiary structure similar to transforming growth factor- $\beta$ .<sup>20</sup> Norrie's disease is a member of the familial exudative vitreoretinopathy (FEVR) syndromes, which are genetically heterogeneous inherited blinding disorders of the retinal vascular system, and to date three other loci have been mapped.<sup>21</sup> Mutations in the Norrie's disease gene have been found in a small subset of patients with severe retinopathy of prematurity (ROP), although defects in this gene do not appear to be a major factor in ROP.<sup>22</sup>

## SORSBY'S MACULAR DYSTROPHY

Sorsby's macular dystrophy is an autosomal dominant disorder characterized by early onset bilateral and multifocal choroidal neovascularization resulting in macular edema, hemorrhage, and exudation. The disease typically begins at about 40 years of age. Missense mutations in the gene that codes for tissue inhibitor metalloproteinase-3 (TIMP-3) have been found in affected individuals.<sup>23</sup> This protein is involved in remodeling of the extracellular matrix. Inactivation of the protein may lead to an increase in activity of the metalloproteinase, which may contribute to the pathogenesis of the disease.<sup>23</sup>

## GYRATE ATROPHY

Hyperornithinemia results from deficiency of the enzyme ornithine ketoacid aminotransferase and has been shown to be the cause of gyrate

atrophy, an autosomal recessive condition characterized by circular areas of chorioretinal atrophy. Mutations in the gene for ornithine ketoacid aminotransferase mapped to chromosome 10q26 have been associated with the disease in affected individuals.<sup>24</sup> Most of the responsible mutations are missense mutations, which presumably result in an inactive enzyme. One mutation has been found in homozygous form in the vast majority of apparently unrelated cases of gyrate atrophy in Finland, an example of a founder effect that produces a common mutation in an isolated population.

Identification of the enzyme defect responsible for this disease makes it an interesting candidate for gene therapy. Previous studies indicated that a lower ornithine level, achieved through a strict low-arginine diet, may retard the progression of the disease.<sup>25</sup> Replacement of the abnormal gene—or genetic engineering to produce a supply of normal enzyme—may result in a reduction of ornithine levels without dietary restrictions.

## COLOR VISION

Defective red–green color vision affects 2%–6% of men and results from a variety of defects that involve the color vision genes. In humans, the three cone pigments—blue, green, and red—mediate color vision. Each visual pigment consists of an integral membrane apoprotein bound to the chromophore 11-*cis* retinal. The genes for the red and green pigments are located on the X chromosome, and the gene for the blue pigment is located on chromosome 7. The X chromosome location of the red and green pigment genes accounts for the X-linked inheritance pattern observed in red or green color vision defects.

The common variations in red or green color vision are caused by the loss of either the red or the green cone pigment (dichromasy) or by the production of a visual pigment with a shifted absorption spectrum (anomalous trichromasy). A single amino acid change (serine to alanine) in the red photopigment gene is the most common color vision variation. Among Caucasian men, 62% have serine at position 180 in the red pigment protein, and 38% have alanine in this position. Men who carry the red pigment with serine at position 180 have a greater sensitivity to long-wavelength radiation than do men who carry alanine at this position.<sup>26</sup> Recent work suggests that gene therapy could correct color vision defects.<sup>27</sup>

## RETINOBLASTOMA

A gene responsible for the childhood eye tumor retinoblastoma was identified in 1986 on chromosome 13q14.<sup>28</sup> The gene product is involved in regulation of the cell cycle. Absence of this protein in an embryonic retinal cell results in the uncontrolled cell growth that eventually produces a tumor.<sup>29</sup> Susceptibility to hereditary retinoblastoma is inherited as an autosomal dominant trait. Mutations in the retinoblastoma gene result in underproduction of the protein product or production of an inactive protein product. A retinal cell that has only one mutant copy of the retinoblastoma gene does not become a tumor. However, inactivation of the remaining normal copy of the retinoblastoma gene is very likely in at least one retinal cell out of the millions present in each retina. Among individuals who inherit a mutant copy of the retinoblastoma gene, 90% sustain a second hit to the remaining normal copy of the gene and develop a tumor (Fig. 1.2.5).<sup>30</sup> Fifty percent of the offspring of individuals affected by hereditary retinoblastoma will inherit the mutant copy of the gene and are predisposed to develop the tumor. Approximately 10% of individuals who inherit a mutation do not sustain a second mutation and do not develop a tumor. The offspring of these “carrier” individuals also have a 50% chance of inheriting the mutant copy of the retinoblastoma gene (see Fig. 1.2.5).

## ALBINISM

Autosomal recessive diseases often result from defects in enzymatic proteins. Albinism is the result of a series of defects in the synthesis of melanin pigment.<sup>31</sup> Melanin is synthesized from the amino acid tyrosine, which is first converted into dihydroxyphenylalanine through the action of the copper-containing enzyme tyrosinase. An absence of tyrosinase results in one form of albinism. Mutations in the gene that codes for tyrosinase are responsible for tyrosinase-negative ocular cutaneous albinism. Most of the mutations responsible for this disease cluster in the binding sites for copper and disrupt the metal ion–protein interaction necessary for enzyme function.<sup>32</sup> Both copies of the gene for tyrosinase must be mutated before a significant interruption of melanin production occurs. Heterozygous individuals do not have a clinically apparent phenotype, which suggests that one functional copy of the gene produces sufficient active enzyme for the melanin level to be phenotypically normal (Fig. 1.2.6).

## LEBER'S OPTIC NEUROPATHY

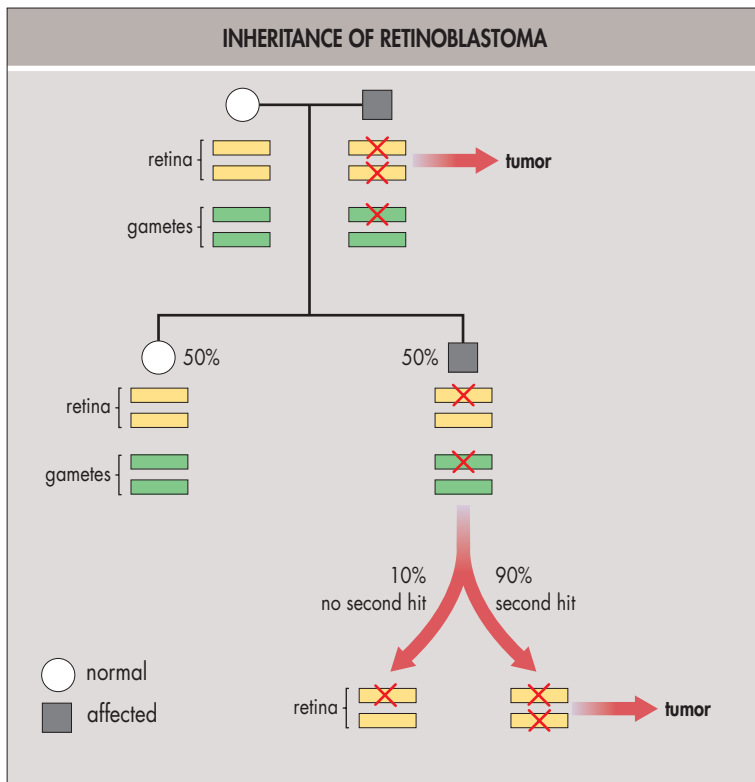

Mutations in mitochondrial DNA are an important cause of human disease. Disorders that result from mutations in mitochondrial DNA demonstrate a maternal inheritance pattern. Maternal inheritance differs from mendelian inheritance, in that men and women are affected equally, but only affected females transmit the disease to their offspring. The characteristic segregation and assortment of mendelian disorders depend on the meiotic division of maternal and paternal chromosomes found in the nucleus of cells. In contrast, mitochondrial DNA is derived from the maternal egg and replicates and divides with the cell cytoplasm by simple fission. A mutation that occurs in mitochondrial DNA is present in all cells of the organism, which includes the gametes. Female eggs have abnormal mitochondria that may be passed to offspring. Sperm contain mitochondria but do not transmit mitochondria to the fertilized egg. A man who carries a mitochondrial DNA mutation may be affected by the disease, but he cannot transmit the disease to his offspring.

Leber's hereditary optic neuropathy (LHON) was one of the first diseases to be recognized as a mitochondrial DNA disorder.<sup>33</sup> In familial cases

of the disease, all affected individuals were related through the maternal lineage, consistent with inheritance of human mitochondrial DNA.

Patients affected by LHON typically present in midlife with acute or subacute, painless, central vision loss that results in a permanent central scotoma and loss of sight. The manifestation of the disease varies tremendously, especially with respect to onset of visual loss and severity of the outcome. The eyes may be affected simultaneously or sequentially; the disease may progress rapidly over a period of weeks to months or slowly over several years. Within a family, the disease may also vary among affected members.

Several factors contribute to the variable phenotype of this condition. Certain mutations are associated with more severe disease, and some mitochondrial DNA haplotypes appear to be associated with more severe disease.<sup>34</sup> Another important factor that affects the severity of the disease is the heteroplasmic distribution of mutant and normal mitochondria. Not all mitochondria present in diseased tissue carry DNA mutations. During cell division, mitochondria and other cytoplasmic organelles are distributed arbitrarily to the daughter cells. Consequently, the daughter cells are likely to have unequal numbers of mutant and normal mitochondria (Fig. 1.2.7). Because the diseased mitochondria are distributed to developing tissues, some tissues accumulate more abnormal mitochondria than others. Hence, some individuals have more abnormal mitochondria in the optic nerve and develop a more severe optic neuropathy.

**Fig. 1.2.5 Inheritance of Retinoblastoma.** Individuals who inherit a mutation in the retinoblastoma gene are heterozygous for the mutation in all cells of the body. The “second hit” to the remaining normal copy of the gene occurs in a developing retinal cell and leads to tumor formation (see text for explanation).

## CONGENITAL FIBROSIS SYNDROMES AND DISORDERS OF AXON GUIDANCE

Congenital fibrosis of the extraocular muscles and Duane's syndrome are inherited forms of congenital fibrosis and strabismus. At least 20 genes contribute to these conditions and other disorders of axon guidance,<sup>35</sup> with the *ARIX/PHOX2A* genes causing congenital fibrosis of extraocular muscles type 2<sup>36</sup> and the *SALL4* gene causing Duane's radial ray syndrome.<sup>37</sup>

## AUTOSOMAL DOMINANT OPTIC ATROPHY

Of the inherited optic atrophies, autosomal dominant Kjer optic atrophy is the most common. This disease results in a progressive loss of visual acuity, centrocecal scotoma, and bilateral temporal atrophy of the optic nerve. The onset is typically in the first two decades of life. The condition is inherited as an autosomal dominant trait with variable expressivity, and mutations in *OPA1* have been found in a number of affected families.<sup>38,39</sup> *OPA1* codes for a dynamin-related GTPase that is targeted to mitochondria and may function to stabilize mitochondrial membrane integrity. It is interesting that this gene and the gene responsible for another optic atrophy, Leber's hereditary optic atrophy (see earlier), both function in the mitochondria, emphasizing the critical role of mitochondria in optic nerve function.

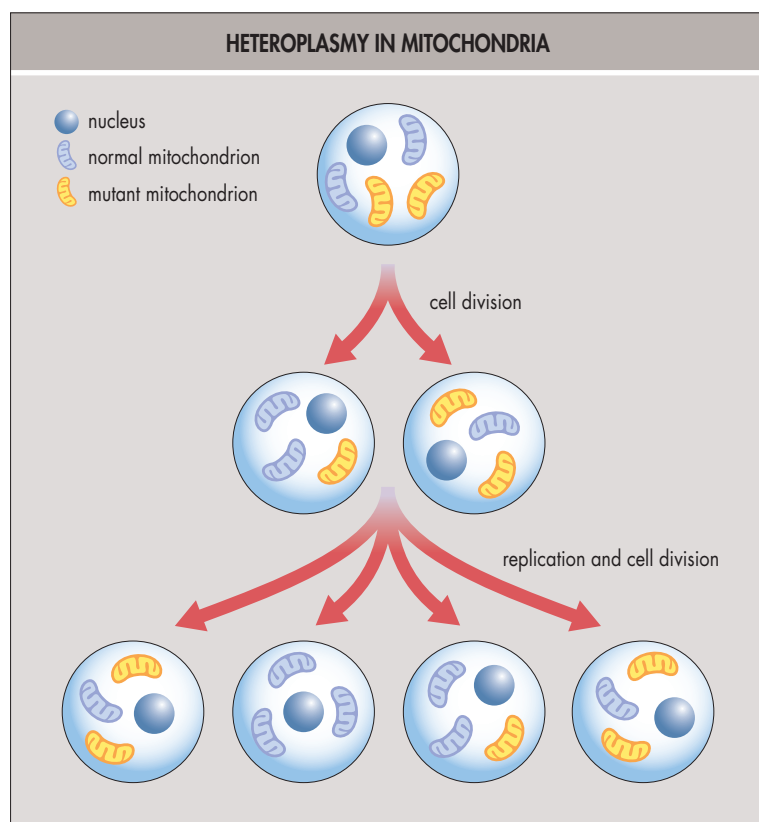

## COMPLEX TRAITS

Human phenotypes inherited as polygenic or “complex” traits do not follow the typical patterns of mendelian inheritance. Complex traits are relatively

**Fig. 1.2.6 Metabolism of Tyrosine to Produce Melanin.** In the final step, dopamine is converted into an indole derivative that condenses to form the high-molecular-weight pigment melanin.

**Fig. 1.2.7 Heteroplasmy in Mitochondria.** Daughter cells that result from the division of a cell that contains mitochondria with mutant DNA may contain unequal numbers of mutant mitochondria. Subsequent divisions lead to a population of cells with different numbers of normal and abnormal mitochondria.

common disorders. Generally, DNA variants associated with these disorders are not causal but influence disease susceptibility.<sup>40</sup> Environmental factors may also contribute to complex disease risk. For example, genetic variants in complement factor H (CFH) and *LOC37718* are known to be major genetic risk factors for age-related macular degeneration,<sup>41–44</sup> and combined with smoking the risk is increased.<sup>45</sup> The genome-wide association study (GWAS) approach has also successfully identified genes contributing to other common complex ocular conditions and traits,<sup>40</sup> including primary open-angle glaucoma,<sup>46,47</sup> primary angle-closure glaucoma,<sup>48</sup> exfoliation syndrome and glaucoma,<sup>49,50</sup> myopia,<sup>51,52</sup> and Fuchs' endothelial dystrophy.<sup>53</sup>

# Genetic Testing and Genetic Counseling

# 1.3

Janey L. Wiggs

**Definition:** A genetic test is any clinical or laboratory investigation that provides information about the likelihood that an individual is affected with a heritable disease. The majority of genetic tests are based on molecular evaluations of genomic DNA designed to identify the DNA mutations responsible for the disease.

**Key Features**

- Indications and methods for genetic testing for ocular disorders.
- Genetic counseling and ethical issues.

GENETIC TESTING

Role of Genetic Testing in the Clinic

DNA-based genetic tests can identify individuals at risk for disease before any clinical evidence is present (presymptomatic testing).<sup>1</sup> This information coupled with effective genetic counseling and clinical screening can be useful. An effective presymptomatic test needs to meet the specificity and sensitivity expectations for any clinical test. Sensitivity is the number of affected individuals that are positive for a test compared with the total number of affected individuals (including those that tested negative for the test). Specificity is the number of unaffected individuals that are negative for the test compared with the total number of unaffected individuals tested (including those that tested positive for the test) (Fig. 1.3.1).

The identification of a mutation responsible for a disease through DNA-based genetic testing can establish a molecular diagnosis. For some disorders, such as juvenile open-angle glaucoma caused by mutations in *MYOC*,<sup>2</sup> specific mutations have been correlated with severity of disease or other clinical features that are useful prognostically. A molecular diagnosis may also help guide therapy and is required before gene-based therapies can be utilized. For example, mutations in a number of different genes can cause Leber’s hereditary amaurosis, but only those patients with disease due to mutations in *RPE65* will benefit from novel *RPE65*-based therapies using gene replacement.<sup>3</sup>

SPECIFICITY AND SENSITIVITY		
	Affected individuals	Unaffected individuals
Individuals positive for test	A	B
Individuals negative for test	C	D
Sensitivity $\frac{A}{A+C}$ Specificity $\frac{D}{B+D}$		

**Fig. 1.3.1 Definition of Sensitivity and Specificity for a Laboratory Test.** Sensitivity is defined as the number of affected individuals positive for the test (A) divided by the total number of affected individuals tested (A + C). Specificity is defined as the number of unaffected individuals negative for the test (D) divided by the total number of unaffected individuals tested (B + D).

Methods for DNA-Based Genetic Testing

Although genetic testing can be performed using DNA, RNA, or protein, DNA is the easiest to work with, and most genetic tests use this as the starting material. A biological sample from the patient is needed before genetic testing can be performed. The inclusion of family members may help the evaluation, but they are not absolutely required. DNA for testing can be obtained from a number of sources, including blood samples, mouthwash samples or buccal swabs, archived pathology specimens, or from hair.<sup>4-6</sup>

Genomic DNA sequencing is the most commonly used method to detect mutations. For many disorders, sequencing the entire responsible gene is necessary, including all exons, immediate flanking intron sequences with splice signals and 5’ and 3’ flanking regulatory regions. Some disorders are caused by a specific mutation in a gene, and genetic testing can be limited to an evaluation of a single gene. For other diseases, however, such as the inherited retinal degenerations, sequencing multiple genes may be required before a causative mutation is identified. For diseases with many causative genes, a panel test that allows for sequencing all genes at once is both more effective and more efficient.<sup>7</sup> Alternatively, whole exome sequencing (WES) that captures and sequences all coding regions of the genome can also be a preferred approach for disorders with many possible genetic mutations.<sup>8</sup> Genomic DNA sequencing will not usually identify large chromosomal abnormalities, including large copy number variations (deletions or insertions) or chromosomal translocations. Other techniques are necessary to detect large chromosomal abnormalities, including karyotyping and multiplex ligation-dependent probe amplification (MLPA).<sup>9,10</sup> For diseases that are caused primarily by a limited set of mutations (for example, the three mutations that commonly cause Leber’s hereditary optic neuropathy (LHON),<sup>11</sup> specific tests such as allele-specific polymerase chain reaction (PCR) amplification or TaqMan assays can be used and can be more efficient than sequencing the entire gene (Table 1.3.1).

Current Recommendations for Genetic Testing for Ophthalmic Diseases

Currently, genetic testing is indicated for patients with clinical evidence of a disorder whose causative genes have been identified and for which

TABLE 1.3.1 Common Types of Genetic Tests

Method	Indication	Example
Single gene DNA sequencing	Different mutations distributed throughout a single gene are known to cause the inherited condition	Sequencing <i>OPA1</i> in patients with autosomal dominant optic neuropathy
Multiple gene DNA sequencing	Mutations in multiple genes are known to cause the condition	Inherited retinal degenerations
Multiplex ligation-dependent probe amplification (MLPA)	Detects deletions and duplications in genes known to cause the condition and that may be missed by sequence-based approaches	MLPA testing for <i>PAX6</i> deletions in patients with aniridia
TaqMan assay or allele-specific assay	Detects a single DNA base pair change and is used if a small set of mutations are primarily the cause of the condition	Three mutations commonly cause Leber’s hereditary optic neuropathy (LHON)
Karyotype	Detects large chromosomal rearrangements including deletions, duplications, and translocations	Down syndrome

the identification of the genetic mutation contributing to the disease has sufficient specificity and sensitivity that testing will be clinically useful. Serious failures of a diagnostic test are false positives (individuals without the disease who test positively) and false negatives (individuals with the disease who test negatively). Although genes have been identified for some common complex disorders such as age-related macular degeneration, primary open-angle glaucoma, and exfoliation syndrome, in general, testing for these mutations is not sufficiently sensitive and specific that the test results are clinically meaningful. For example, over 90% of patients with exfoliation syndrome carry one of two missense changes in *LOXL1*; however, up to 80% of normal individuals also carry these same DNA sequence variants.<sup>12</sup> Clearly the identification of these missense mutations alone is not clinically useful. Examples of genetic tests that are useful include *RPE65* for Leber's hereditary amaurosis,<sup>13</sup> *PAX6* for aniridia,<sup>14</sup> *MYOC* for early onset primary open-angle glaucoma,<sup>15</sup> and *OPA1* for optic neuropathy,<sup>16</sup> as well as many other genes that are known to cause inherited ocular conditions.<sup>17</sup>

## CLIA Laboratories

Laboratories in the United States offering genetic testing must comply with regulations under the Clinical Laboratory Improvement Amendments of 1988 (CLIA). The Centers for Medicare and Medicaid Services administers CLIA and requires that laboratories meet certain standards related to personnel qualifications, quality control procedures, and proficiency testing programs in order to receive certification. This regulatory system was put in place to encourage safe, accurate, and accessible genetic tests. In addition to ensuring that consumers have access to genetic tests that are safe, accurate, and informative, these policies encourage the development of genetic tests, genetic technologies, and the industry that produces these products. A number of CLIA-certified laboratories performing genetic testing for eye diseases exist in the United States. For a list of CLIA-certified laboratories participating in the National Eye Institute (NEI)-sponsored eyeGENE network, see the NEI website at <http://www.nei.nih.gov>. CLIA-certified laboratories offering genetic testing can also be found at GeneTests: <https://www.genetests.org/>.

## Genetic Reports

A genetic test report is a sensitive document that is the main form of communication between the CLIA laboratory and the physician requesting the genetic test. Genetic test reports may be shared with the patient and with genetic counselors. The report should include (1) the type of genetic test performed (i.e., sequencing or other methodology), (2) the gene or genes that were evaluated, (3) the results of the testing, (4) information about the pathogenicity of the sequence variants, (5) recommendations for clinical follow-up based on the results of testing, and (6) literature references providing additional information about the genes and mutations responsible for the disease. The report should be written clearly and have appropriate contact information.

Novel DNA sequence changes are frequently found as a result of genomic DNA sequencing. New DNA sequence changes (variants) may be benign polymorphisms or causative mutations. Additional studies must be done before the sequence change can be designated as disease causing. Demonstrating that the mutant protein has an abnormal function or evaluation of the mutant gene in an animal model would be an ideal test of pathogenicity, but these approaches are time consuming and may not be possible. Current approaches to evaluate the pathogenicity of a novel DNA sequence variant are based on (1) population data, (2) computational and predictive data from *in silico* estimates for pathogenicity such as SIFT<sup>18</sup> and PolyPhen-2,<sup>19</sup> (3) functional data, and (4) segregation data for families.<sup>20</sup>

## GENETIC COUNSELING

Genetic counseling has become an important part of any clinical medicine practice. In 1975 the American Society of Human Genetics adopted this descriptive definition of genetic counseling<sup>21</sup>:

Genetic counseling is a communication process which deals with the human problems associated with the occurrence or risk of occurrence of a genetic disorder in a family. This process involves an attempt by one or more appropriately trained persons to help the individual or family to (1) comprehend the medical facts including the diagnosis, probable course of the disorder, and the available management, (2) appreciate the way heredity contributes to the disorder and the risk of recurrence in specified relatives,

(3) understand the alternatives for dealing with the risk of recurrence, (4) choose a course of action that seems to them appropriate in their view of their risk, their family goals, and their ethical and religious standards and act in accordance with that decision, and (5) to make the best possible adjustment to the disorder in an affected family member and/or to the risk of recurrence of that disorder.

## Clinical Evaluation and Family History

An accurate diagnosis is the first step in productive genetic counseling. The patient-physician discussion of the natural history of the disease and of its prognosis and management is entirely dependent on the correct identification of the disorder that affects the patient. Risk assessment for other family members and options for prenatal diagnosis also depend on an accurate diagnosis. In some cases, appropriate genetic testing may help establish the diagnosis. Examination of other family members may be indicated to determine whether a particular finding is hereditary.

A complete family history of the incidence of the disorder is necessary to determine the pattern of inheritance of the condition. The mode of inheritance (i.e., autosomal dominant, autosomal recessive, X-linked, or maternal) must be known to calculate the recurrence risk to additional family members, and it helps confirm the original diagnosis. For the record of family information, the gender and birth date of each individual and his or her relationship to other family members are indicated using the standard pedigree symbols. It is also helpful to record the age of onset of the disorder in question (as accurately as this can be determined). The pedigree diagram must include as many family members as possible. Miscarriages, stillbirths, and consanguineous parents are indicated.

Occasionally a patient may appear to be affected by a condition that is known to be inherited, but the patient is unable to provide a family history of the disease. Several important explanations for a negative family history must be considered before the conclusion is made that the patient does not have a heritable condition. First, the patient may not be aware that other family members are affected by the disease. Individuals frequently are reluctant to share information about medical problems, even with close family members. Second, many disorders exhibit variable expressivity or reduced penetrance, which means that other family members may carry a defective gene that is not expressed or results in only a mild form of the disease that is not readily observed. Third, false paternity may produce an individual affected by a disease that is not found in anyone else belonging to the acknowledged pedigree. Genetic testing can easily determine the paternity (and maternity) of any individual if blood samples are obtained from relevant family members. Fourth, a new mutation may arise that affects an individual and may be passed to offspring, even though existing family members show no evidence of the disease.

## Risk Prediction Based on Inheritance

Once the diagnosis and family history of the disorder are established, risk prediction in other family members (existing and unborn) may be calculated. The chance that an individual known to be affected by an autosomal dominant disorder will transmit the disease to his or her offspring is 50%. This figure may be modified depending on the penetrance of the condition. For example, retinoblastoma is inherited as an autosomal dominant trait, and 50% of the children of an affected parent should be affected. However, usually only 40%–45% of the children at risk are affected, because the penetrance of the retinoblastoma trait is only 80%–90%, which means that 5%–10% of children who have inherited an abnormal copy of the retinoblastoma gene do not develop ocular tumors.

An individual affected by an autosomal recessive trait will have unaffected children unless he or she partners with another individual affected by the disease or with an individual who is a carrier of the disease. Two individuals affected by an autosomal recessive disease produce only affected offspring. (There are some rare exceptions to this rule. If the disease is the result of mutations in two different genes, it is possible for two individuals affected by an autosomal recessive trait to produce normal children. Also, in rare cases, different mutations in the same gene may compensate for each other, and the resultant offspring will be normal.) If an individual affected by an autosomal recessive disease partners with a heterozygous carrier of a gene defect responsible for that disorder, the chance of producing an affected child is 50%. Among the offspring of an individual affected by an autosomal recessive disease, 50% will be carriers of the disorder. If one of these offspring partners with another carrier of the disease, the chance of producing an affected child is 25%.

**BOX 1.3.1 Types of Clinical Genetics Services and Programs****Center-Based Genetics Clinic**

- Outreach clinics
- Inpatient consultations

**Specialty Clinics**

- Metabolic clinic
- Spina bifida clinic
- Hemophilia clinic
- Craniofacial clinic
- Other single-disorder clinics (e.g., neurofibromatosis type 1 clinic)

**Prenatal Diagnosis Program: Perinatal Genetics**

- Amniocentesis/chorionic villus sampling clinics
- Ultrasound program
- Maternal serum  $\alpha$ -fetoprotein program

**Genetic Screening**

- Newborn screening program/follow-up clinic
- Other population-screening programs (e.g., for Tay–Sachs disease)

**Education/Training**

- Healthcare professional
- General public
- School system
- Teratology information services

X-linked disorders are always passed from a female carrier who has inherited a copy of an abnormal gene on the X chromosome received from either her mother (who was a carrier) or her father (who was affected by the disease). Man-to-man transmission is not seen in diseases caused by defects in genes located on the X chromosome. Among sons born to female carriers of X-linked disorders, 50% are affected by the disease, and 50% of daughters born to female carriers of X-linked disorders are carriers of the disease. All the daughters of men affected by X-linked disorders are carriers of the disease.

Mitochondrial disorders are inherited by sons and daughters from the mother. The frequency of affected offspring and the severity of the disease in affected offspring depend on the number of abnormal mitochondria present in the egg that gives rise to the affected child. Diseased and normal mitochondria are distributed randomly in all cells of the body, including the female gametes. As a result, not all the eggs present in a woman affected by a mitochondrial disorder have the same number of affected mitochondria (heteroplasmy). Men affected by mitochondrial disorders only rarely have affected children, because very few mitochondria in the developing embryo are derived from the sperm used to fertilize the egg.<sup>22</sup>

With careful diagnosis and family history assessment, even sporadic cases of heritable disorders are identifiable. In such cases, an estimate of recurrence risk can be calculated using the available pedigree and clinical information and the statistical principle called Bayes' theorem. These individuals should be referred to clinical genetics services such as those commonly found in hospital settings (Box 1.3.1).

**Indications to Refer for Genetic Counseling****Known Inherited Condition**

Genetic counseling can be useful for a family with a member affected by an established diagnosis. In this case the goal of the counseling is to describe recurrence risks for other family members. For example, if a child has retinoblastoma and a positive family history, the family may be referred for genetic counseling to review recurrence risks. If diagnostic testing has been performed, that can also be discussed and will aid in the presentation of the recurrence risks, especially if other family members have been tested.

**Ocular and Systemic Congenital Anomalies**

Individuals with multiple ocular and systemic anomalies may or may not fit into a particular syndrome. In these situations, the experience of a geneticist in recognizing malformation patterns and understanding the variability of genetic conditions can aid diagnosis. If an underlying cause is identified, relatives can then undergo genetic counseling.

**Specific Eye Diseases**

A genetic evaluation is important for families with inherited eye diseases. Many ophthalmological diseases have a well-documented inheritance pattern, and describing the inheritance to family members may help identify affected relatives who could be diagnosed and treated early in the course of the disease. This is especially important in families with conditions such as dominantly inherited juvenile glaucoma.

**Ocular Defects Associated With Genetic Diseases**

Many genetic diseases have associated ocular defects. For example, a diagnosis of neurofibromatosis type 1 may be made in a child because Lisch nodules were detected on a clinical examination.<sup>23</sup> The child and family should be referred for genetic counseling to help define the recurrence risks for other family members.

**Confidentiality**

Confidentiality is an important issue in genetic testing and genetic counseling. Confidentiality issues should be discussed before the initiation of testing so there is consensus on how results are reported, who receives results, and where the information is documented.

# Light

Scott E. Brodie

## 2.1

**Definitions:**

Light – Electromagnetic energy detectable by the eye.  
Geometrical Optics – The properties of light governed by propagation in straight lines, refraction, and reflection.  
Physical Optics – The properties of light described by wave phenomena such as interference, diffraction, and polarization.  
Quantum Optics – The properties of light described by absorption and emission of energy in discrete quanta, proportional to frequency.

**Key Features**

- Specular Reflection – Light reflects off smooth surfaces so that the angle of incidence equals the angle of reflection.
- Snell’s Law – The relationship between the bending of light at an interface surface to the speed of light on either side of the interface.
- Vergence Equation – The relationship between the power of a lens and the location of the images it forms.

**INTRODUCTION**

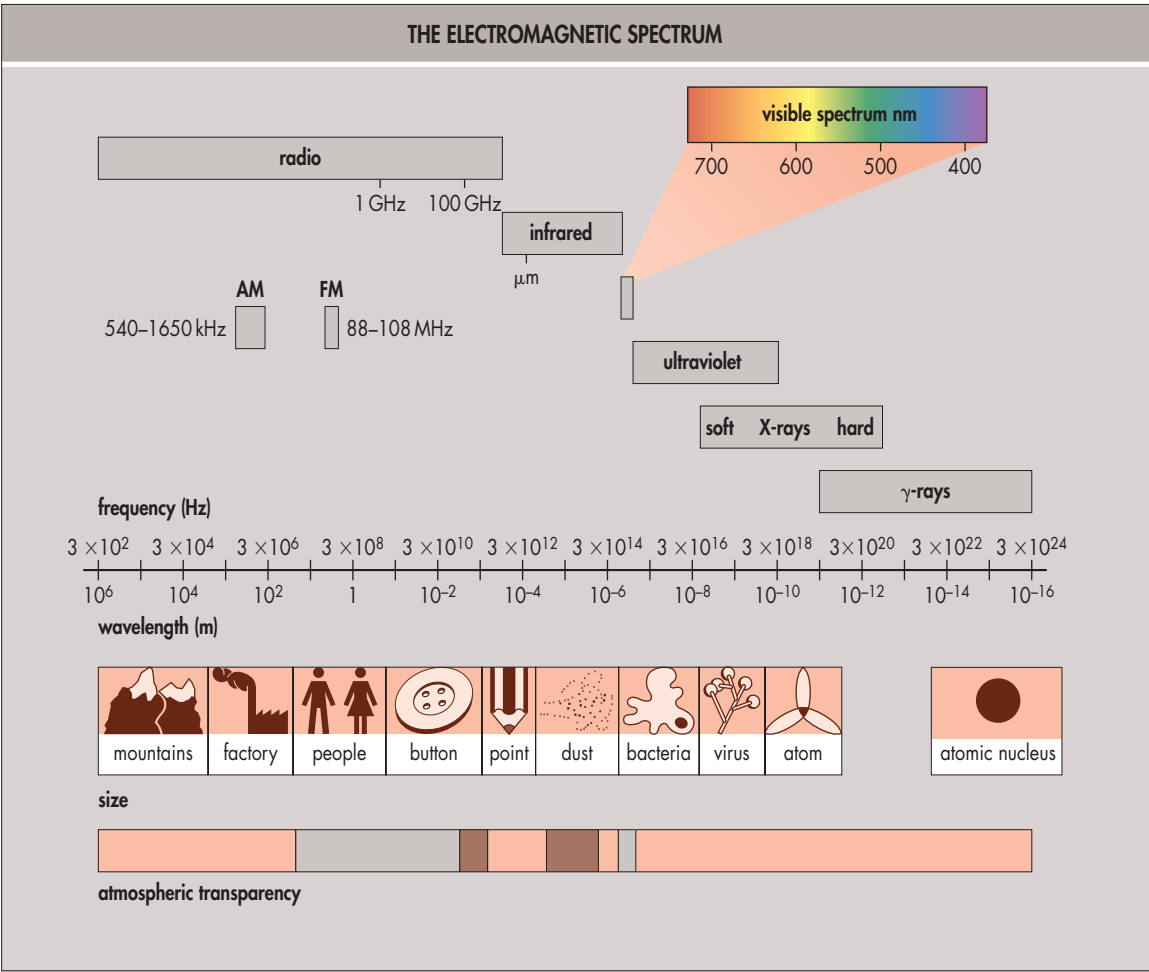

Visible light is the portion of the electromagnetic spectrum that can be detected by the eye. In practice, this ranges from wavelengths of about

750 nm (red) to about 440 nm (violet). Longer wavelengths may be discernable as heat (“infrared”) and can be detected by suitable photographic emulsions and electronic camera chips. Shorter wavelengths (“ultraviolet”) are sometimes visible in eyes after removal of the crystalline lens and can be seen by some insects (Fig. 2.1.1).

The behavior of light under ordinary circumstances is very familiar, but careful observations reveal important subtleties that have fascinated scientists for hundreds of years. In general, the behavior of light in detail depends on the scale of the objects with which it interacts.

Interactions between light and large objects (relative to the wavelength of the light) generally follow simple geometrical rules and come under the heading of “geometrical optics.” This is the regime of typical human experience—light rays travel in straight lines through homogeneous media but may be reflected by polished smooth surfaces or may be refracted (bent) as they pass from one medium to another. These interactions of light with matter are governed by the law of (specular) reflection and Snell’s law, respectively. Geometrical optics is the appropriate tool for understanding the use of lenses for the formation of images—as in the human eye—or as modified by lenses such as spectacles, contact lenses, or intraocular lens implants.

When the dimensions of optical systems are comparable to the wavelength of the light passing through them, the effects of interference become evident, demonstrating the “wave-like” properties of light. Perhaps the most common example is the diffraction of light as it passes through

**Fig. 2.1.1 The Electromagnetic Spectrum.** The pictures of mountains, people, buttons, viruses, etc., are used to produce a real (i.e., visceral) feeling of the size of some of the wavelengths. In the bar at the bottom of the figure, gray portions of the bar indicate regions of the spectrum to which the atmosphere is transparent. (Adapted from Zeilik M. *Astronomy: the evolving universe*. 3rd ed. New York: Harper & Row; 1982.)

finite apertures, such as the pupil of the human eye. Because the light bends slightly under these circumstances, diffraction limits the sharpness of images formed through small apertures. Wave properties of light also are seen in the phenomena of polarization and are exploited in such optical instruments as interferometers (which accurately measure very small distances) and clinical devices such as the optical coherence tomographer, which exploits interference between beams of light that have scattered from various surfaces within the eye to provide high-resolution images of ocular tissues. These phenomena are discussed later under the heading of “Wave Properties of Light.”

At the smallest scales and energies, the quantum behavior of light becomes evident. Quantum effects are responsible for the operation of lasers, the characteristic absorption and emission spectra of various materials, and the phenomena of fluorescence and phosphorescence.

## GEOMETRICAL OPTICS

Under ordinary conditions, light travels through homogeneous media in straight lines. This can be exploited by simple devices such as the “camera obscura” or pinhole camera, which forms images of bright objects by selecting a single ray of light from each point in the source object that threads through a small aperture to form an inverted image on a convenient surface beyond the pinhole. Although these images enjoy an excellent depth of field, bringing objects both near and far into sharp focus, the small aperture limits the amount of light available to form the image (Fig. 2.1.2).

On the other hand, the paths of light rays can be altered by reflection or refraction. In reflection, the incoming ray of light reverses direction to create equal angles between the incoming ray and the exiting ray, as measured from a line through the point of contact perpendicular to the reflecting surface (the “surface normal”). This is the “law of (specular) reflection.” Specular (mirror-like) reflection is seen as light encounters smoothly polished surfaces, such as mirrors, and still pools of liquids, such as water or mercury. Flat reflecting surfaces recreate accurate reproductions of the source objects (with, of course, the left–right direction reversed). Curved reflecting surfaces can be used to magnify or minify the source objects, as used for special purposes such as telescopes, shaving mirrors, or the minifying mirrors rearview mirrors used in automobiles (Fig. 2.1.3).

When light traverses a boundary between two transparent media where the speed of light differs between the two materials, the path of the light may be deflected from a straight line by the process of refraction.<sup>1</sup>

The deviation is described by “Snell’s law” as follows. First, compute the “refractive index” of each material as the ratio of the speed of light in a

vacuum divided by the speed of light in the medium—the refractive index is often denoted by the letter  $n$ , and is always greater than 1.0 for material media, as light will always travel through a material medium more slowly than through a vacuum. If we measure the angle between the incoming light ray and the surface normal at the point of contact (the “angle of incidence”) and compare it with the angle between the surface normal and the outgoing ray that emerges from the point of contact as the light moves away from the interface in the second medium, we have

$$n_1 \sin \theta_1 = n_2 \sin \theta_2$$

where  $n_1$  and  $n_2$  are the refractive index of the first and second material, respectively, and  $\theta_1$  and  $\theta_2$  are the angles made by the incident and emerging rays with the surface normal (Fig. 2.1.4).

In practice, if the light goes from a “rarer” medium, such as air (with a greater velocity of light and thus a smaller refractive index), to a “denser” medium (with a slower velocity of light and thus a greater refractive index), such as water or glass, the light will bend *toward* the surface normal. (Of course, this use of the word “dense” has nothing to do with the specific gravity of the materials.) Light that travels from a “slow” medium to a medium with a greater velocity of light will bend *away* from the surface normal.

The bending of light across such an interface is readily appreciated when looking at objects in a pool of water from the air above, where objects are typically seen as farther away than they really are because the light from the objects bends toward the observer as it passes from the water to the air (Fig. 2.1.5).

Ordinary prisms work the same way. Light passing through a prism is bent toward the base of the prism. Objects viewed through a prism are seen displaced toward the apex. The strength of a prism is usually given in terms of “prism diopters”—a prism that deflects a beam of light by  $d$  cm at a distance 1.0 m from the prism is said to have a strength of  $d$  prism diopters, usually abbreviated “Δ.”

If the angle of incidence for light going from a “slow” to a “fast” medium exceeds the “critical angle” where  $\sin \theta = n_2/n_1$ , then Snell’s law cannot be satisfied, and the light ray is reflected at the interface rather than refracted across it. This “total internal reflection” is employed by prisms in high-quality binoculars, for example (Fig. 2.1.6).

When light passes through a curved surface such as the surface of a lens, the deflection depends in detail on the shape of the surface. For lenses with spherical surfaces, for which one can determine a geometrical center of curvature, and for light rays that closely approximate the line between the source objects and the center of curvature (the “optic axis”), one can use Snell’s law to show that the lens will form a pointlike image of a point source and derive simple rules relating the location of the source objects, the curvature (or power) of the lens, and the location of the image formed by the lens. This is referred to as “stigmatic imagery” (Fig. 2.1.7).

Stigmatic imagery is strictly possible only for “paraxial” rays and lenses with relatively small apertures (though larger than the pinhole apertures described earlier). Nevertheless, this formulation of geometrical optics is very useful in a wide variety of settings, even when the strict assumptions are not met. For example, in the human eye, strict stigmatic imaging is

**Fig. 2.1.2 The Camera Obscura.** (From Wikipedia “Camera Obscura”; public domain.)

**Fig. 2.1.3 Specular Reflection.** (From Wikipedia, “Specular Reflection”; available for unrestricted use from Creative Commons.)

**Fig. 2.1.4 Snell’s Law.** (From Wikipedia, “Snell’s Law”; public domain.)

possible only when the pupil is fairly small, but because awareness of the sharpness of the image formed on the retina by the optics of the eye is dominated by the image presented to the fovea, the paraxial regime remains an adequate description and is routinely used to guide the prescription of spectacle lenses and contact lenses.

## BASIC STIGMATIC OPTICS

A convex lens will image the light from an infinitely distant object (such as a star) at a finite distance, say  $f$ , from the lens on the side opposite from the source. This distance is referred to as the focal length of the lens and is measured in meters. The “power” of the lens,  $P$ , is given by the equation  $P = 1/f$ . In this context, the units for lens power are referred to as “diopters” and abbreviated “D.” For objects closer than infinity, the image location is determined by the relation

$$1/u + P = 1/v, (*)$$

where  $u$  is the distance in meters from the lens to the source object (objects to the left of the lens are considered to be at distances less than 0); and  $v$  is the distance from the lens to the image. This formula is referred to as the vergence equation. In practice, if an image is formed to the right of such a lens, increasing the power  $P$  will pull the image closer to the lens; reducing the power  $P$  will push it farther away.<sup>2</sup>

**Fig. 2.1.5 Refraction at an Air–Water Interface.** The portion of the soda straw seen through the surface of the water is closer than it appears. (After Wikipedia, “Refraction”; available for unrestricted use from Creative Commons; original figure has been truncated.)

For thin lenses, the power of two lenses placed in contact with each other and used as a single lens system is approximately additive:  $P = P_1 + P_2$ .

Lenses can also be fabricated with concave surfaces. These lenses, which are assigned powers less than 0, do not form images by themselves but can be used to adjust the power of convex lenses by means of the addition formula above. Placing such a lens adjacent to an existing lens system can reduce the effective power, for example, pushing an image farther to the right, as described earlier.

If light approaches or leaves a lens through a medium other than air or a vacuum (with  $n = 1.0$ ), the equation (\*) must be modified as follows:

$$n_1/u + P = n_2/v$$

where  $n_1$  and  $n_2$  are the refractive indices of the media to the left and right of the lens, respectively.

If lenses are used in combination but spaced apart, the image formed by the first lens encountered by the light becomes the source for the next lens in sequence, and the effect of each lens in the sequence is thus analyzed in turn.

For example, in a myopic eye, the optical power of the cornea and lens system is too great for the axial length of the eye, and images of distant objects are formed in front of the retina. A correcting concave (minus-power) lens placed in front of the eye will move the image farther away from the anterior segment, placing it on the fovea, allowing for clear vision and normal acuity. In a hyperopic eye, the optical power of the anterior segment is too little for the axial length of the eye, and so additional plus-lens power is placed in front of the eye to pull the image forward and clarify the vision. See Section 2.4 for further details.

If light passes through the periphery of a thin lens, it encounters inclined surfaces resembling those of a prism, oriented base-inward for a convex lens or base-outward for a concave lens. In general the deflection is proportional to the power of the lens and the distance of the incident ray from the optical center.

**Fig. 2.1.7 Image Formation by a Biconvex Lens.** (After Wikipedia, “Lens [Optics]”; available through Creative Commons; original figure has been truncated.)

**Fig. 2.1.6 Total Internal Reflection.** (From Wikipedia, “Refraction”; available for unrestricted use from Creative Commons.)

Comparison between the definition of the prism diopter and the definition of dioptric power for lenses yields the “Prentice rule”: The prismatic effect of lens decentration is given by the formula  $d(\Delta) = P \cdot r$ , where  $d$  is the prismatic effect in prism diopters,  $P$  is the power of the lens in diopters, and  $r$  is the distance from the optical axis of the lens to the incident ray of light in centimeters.

## ASTIGMATIC OPTICS

Lens surfaces with more complex shapes than the spherical surfaces discussed earlier cannot form simple point images. The simplest case is that of “toric surfaces” resembling the surface of the side of a rugby ball, an American football, or the outer rim of an automobile tire inner tube (Fig. 2.1.8).

Such a surface has different degrees of curvature in different directions at each point. Typically, the maximal and minimal curvatures occur in perpendicular directions at each location. If the surface is sufficiently regular, it can be characterized as equivalent to a spherical refracting surface taken together with a cylindrical surface, with maximal refracting power in one direction and no power in the perpendicular direction. Such lenses form a complex image of a source object point consisting of two perpendicular “focal lines” at the two distances corresponding to the optical powers of the steepest and flattest meridians of the surface (Fig. 2.1.9).

In practice, such a lens can produce stigmatic imagery with the addition of a correcting cylinder oriented to compensate for the variation in power of the original lens.

More complex surfaces and their optical effects are discussed in Section 2.6 on Wavefront Optics and Optical Aberrations of the Eye.<sup>3</sup>

## WAVE PROPERTIES OF LIGHT

In the nineteenth century, it was realized that light exhibits behaviors suggestive of wave propagation, which cannot be incorporated into the simple geometrical framework described earlier. These include interference,

**Fig. 2.1.8 Toric Surface.** (From Wikipedia, “Toric Lens”; available under GNU Free documentation license.)

**Fig. 2.1.9 Conoid of Sturm.** Astigmatic imaging of a point source by a toric lens forming a complex figure between two perpendicular focal lines. ([From AccessLange: General Ophthalmology / Printed from AccessLange ([accessmedicine.com](http://accessmedicine.com)). Chapter 20, Optics and refraction, Paul Riordan-Eva] Copyright ©2002–2003 The McGraw-Hill Companies. All rights reserved.)

diffraction, polarization, and dispersion. These phenomena are readily understood in terms of the classical Maxwell equations of electricity and magnetism but are reasonably appreciated with less detailed descriptions, which simply identify light with a single transverse wave (that is, a wave that oscillates in a direction perpendicular to the propagation of the light)<sup>4</sup> (Fig. 2.1.10).

## Interference

Suppose monochromatic light passes through a narrow slit and then in turn through one of two narrow slits separated by a small distance and is then allowed to land on a screen. Instead of two stripes, one for each of the final slits, the light creates a pattern of alternating bright and dark stripes. This is apparently due to the variation in the path length from the two slits to each image point on the screen, so that the waves emanating from each slit alternately reach the image screen so that the peaks coincide (producing a bright stripe—“constructive interference”) or so that a peak from one slit coincides with a trough from the other slit (producing a dark stripe—“destructive interference”). As the observation point on the screen moves to one side, the relative distance from each of the final slits varies. When the distances differ by exactly one wavelength, the pattern repeats (Fig. 2.1.11).

**Fig. 2.1.10 Electromagnetic Wave.** An electromagnetic wave consists of an oscillating electric field perpendicular to an oscillating magnetic field. Both fields are perpendicular to the direction of propagation.

**Fig. 2.1.11 The “two-slit experiment.”** (From Wikipedia “Double-slit experiment”; licensed under the Creative Commons Attribution-Share Alike 3.0 Unported license.)

**Fig. 2.1.12** The Airy disc. (From Wikipedia, “Airy disk”; public domain.)

Similar patterns can be seen with light passing through a single slit or round aperture, as the light coming from the edge of the aperture interferes with the light coming from the opposite edge, as if the edges were the “slits” in a two-slit experiment. In the case of a circular aperture, the stripes take the form of concentric rings. The central spot in the pattern is known as the “Airy disc” (Fig. 2.1.12).

In general, the spacing between interference fringes will vary with the wavelength of the source illumination—shorter wavelengths give rise to more narrowly spaced fringes. Narrow slits or spacing between the slits leads to wider spacing between fringes, as greater angles are needed to create path length differences of a half wavelength.

Nearly monochromatic light is needed to observe these effects, so as to produce consistent patterns of peaks and troughs.

## Diffraction

As described earlier, interference of portions of a light beam passing near the opposite edges of a small aperture creates a pattern of fringes that extends beyond the geometrical shadow of the aperture on the screen. In this context, the apparent “spreading out” of the light beyond the geometrical limits of the expected image is referred to as “diffraction.” In most contexts, it is sufficient to consider the diameter of the Airy disc as a useful description of the magnitude of this effect. For monochromatic light of wavelength  $\lambda$ , the angular extent of the Airy disc is given by

$$\sin \theta = 1.22 \lambda / d,$$

where  $d$  is the diameter of the aperture. For the human eye, this is comparable to the diameter of a single foveal cone, suggesting that the optics of the eye have evolved to approach “diffracted limited” resolution (Fig. 2.1.13).

## Polarization

The association of an oscillation perpendicular to the direction of propagation of a light beam endows it with a specific orientation. If this orientation is consistent across the beam of light, it is said to exhibit “polarization.” In practice, polarization is demonstrated by the interactions of light with materials that exhibit a particular, consistent molecular organization, such as certain (“birefringent”) crystals or manufactured materials (Polaroid filters) (Fig. 2.1.14).

Polarized light can also occur in nature when light is reflected from a suitable surface, such as a flat pool of water. The preferred direction of polarization is parallel to the reflecting surface, in this case horizontal. Sunglasses containing filters that preferentially transmit vertically polarized light will selectively block these reflections, which make up the bulk of the annoying stray light seen when driving or boating.

Polarized light filters also are useful in certain eye examinations. Stereoscopic depth perception tests are designed to create separate images for the two eyes, each polarized in one of two perpendicular directions. When viewed through glasses with polarized filters placed perpendicular to each other, each eye can see only one of the test targets, creating a stereoscopic 3-D image. Similar strategies can be used to control which eye sees particular acuity targets to reveal possible malingering.

## Dispersion

Visible light varies in wavelength from red (with the longest wavelengths) to blue and violet (with the shortest wavelengths). All wavelengths travel through a vacuum or through air at the same velocity. However, material media may transmit light at different velocities depending on its wavelength. This phenomenon is referred to as “dispersion,” and it accounts for the ability of prisms to break up white light into its constituent colors,

**Fig. 2.1.13 Resolution of Diffraction Patterns of Two Object Sources of Light.** Two object sources of light ( $S_1$  and  $S_2$ ) cannot be resolved if their diffraction patterns (Airy discs) overlap substantially. Two refraction patterns are produced by a circular aperture placed between two lenses, and resultant patterns of the light intensity distribution and appearance are shown. The central maxima of one diffraction pattern falls on the second minima of the diffraction pattern from the second source; the central maxima of one diffraction pattern falls on the first minima of the diffraction pattern from the second source, and the two images can just be resolved (Rayleigh criterion); the two images merge as one. Bottom right, mosaic of retinal cones with the diffraction pattern superimposed. (Adapted from Jenkins FA, White HE. *Fundamentals of optics*. New York: McGraw-Hill; 1950. p. 290–3; and Emsley HH. *Visual optics*. London: Hatton Press; 1950. p. 47.)

**Fig. 2.1.14 Polarization.** Both transverse waves propagate in the same direction but oscillate in different planes. Here, only the scalar wave approximation is adopted, and only the electric field is shown.

**Fig. 2.1.15 Dispersion of White Light by a Prism.** (From Wikipedia “Prism”; licensed under the Creative Commons Attribution-Share Alike 3.0 Austria license.)

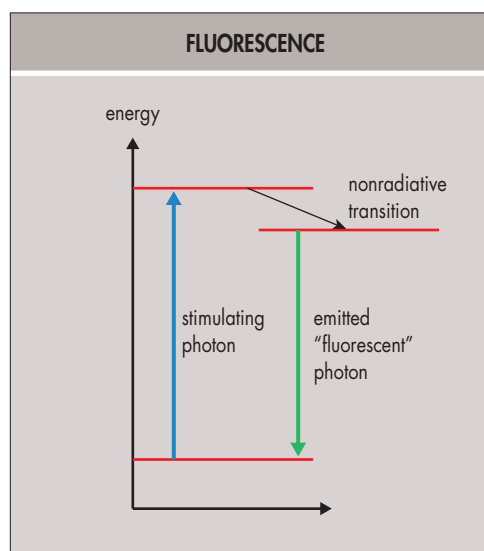

as light of each color is refracted by a prism to slightly different degree (Fig. 2.1.15).

In most optical devices, this effect is something of a nuisance, producing colored fringes at the edge of images. In practice this is corrected in high-quality optics by using lenses of different types of glass in such a way as to cause their dispersion effects to cancel out. In the human eye, this effect is referred to as “chromatic aberration,” which is the basis of the “duochrome” test used to refine measurements of refractive error.

## Quantum Effects

At the smallest scales, the quantum-mechanical nature of the interactions between light and matter become evident. These effects reflect the observation that an energy transfer between light and matter occurs only in fixed amounts (“quanta”) with energy proportional to the frequency of the light, according to Planck’s equation:  $E = h\nu$ , where  $h$  is Planck’s constant.<sup>5</sup>

For example, the electrons in a molecule transition between various energy states by exchanging light energy (“photons”) with the environment. As the various available energy states form a series of discrete values, the energy of the various possible transitions can take only certain discrete values. These are appreciated as the emission lines seen in the spectrum when such a material is heated to incandescence, which are characteristic of the material, or as absorption lines seen when broadband light passes through a gaseous medium, absorbing only light of the frequencies (colors) corresponding to permissible transitions of electrons between allowed energy levels.

**Fig. 2.1.16 Energy Levels in a Hypothetical Fluorescent Molecule.** A relatively high-energy photon raises an electron to the highest level. The electron drops to a nearby level by nonradiative means and then drops to its original low level emitting a lower energy photon than the one originally absorbed.

## Fluorescence and Phosphorescence

In some cases, the energy absorbed by a molecule will be dispersed in stages, initially dropping from one state to a nearby state (the energy released in the form of thermal energy of the molecule, rather than released as a photon), and subsequently the remaining energy released as a photon as the electron returns to its initial base level. In such an event, the energy of the photon that is emitted will be less than that of the photon that was initially absorbed, and so will necessarily be seen as a photon of a different wavelength, shifted toward the red end of the spectrum (Fig. 2.1.16).

If this transition occurs promptly, the effect is referred to as fluorescence. For example, the dye molecule fluorescein, frequently used as a disclosing agent in ophthalmology, absorbs photons in the blue portion of the spectrum but fluoresces a yellow–green color. If the intermediate level is more stable, the intermediate energy state can persist for many hours, resulting in a prolonged release of the light energy as the final energy transition occurs over an extended period. In this case the process is known as phosphorescence.

## Lasers

The operation of laser devices is another important manifestation of a quantum effect. In this case a working medium is “pumped” into a metastable state by absorbing energy from an external source, often a flash of light from an ordinary source.<sup>6</sup> This produces an “inversion,” with an excess of electrons at an elevated energy state. The probability of such electrons dropping to their base energy level is enhanced by interaction with another photon of the same energy as the latent transition—this is referred to as “stimulated emission of radiation.”

In practice, the working medium is contained in a cylindrical cavity with a reflecting mirror at one end and a partially reflecting mirror at the other. After creation of the inversion, as electrons revert to their base level, photons of an energy corresponding to this transition start to bounce back and forth between the two mirrors, stimulating more photon emissions of precisely the same energy. The corresponding light beams accumulate homogeneously in the laser cavity, and eventually the excess energy emerges through the partially silvered mirror as a highly monochromatic beam of light with a very high degree of coherence (all waves with peaks and troughs aligned parallel to the laser cavity mirrors). The resulting laser light can be very accurately collimated into a beam with little angular divergence, suitable for applications from photocoagulation of retinal lesions to serving as a lecture pointing device (Fig. 2.1.17).

**Fig. 2.1.17 Gas Laser.** A typical design consists of a gas-filled cavity, external optical pumping lights, and a resonator that comprises partially and totally reflecting mirrors. Without optical pumping, most of the gas atoms are in lower energy states and incapable of undergoing either spontaneous or stimulated emission. With optical pumping, photons from the external lights are absorbed by the gas atoms, which raises the energy of the atoms and makes them capable of undergoing spontaneous or stimulated emission. Ultimately, the majority of atoms are in excited states—a population inversion. One of the higher energy atoms spontaneously emits a photon that produces stimulated emissions as it passes by other high-energy atoms. As the photons are reflected back and forth across the cavity multiple times, a chain reaction of stimulated emissions is produced.

## 2.2

**Definition:** The classic optics of the eye are best understood in terms of the optical characteristics of its components—the cornea, pupil, crystalline lens, and retina—and how they function in combination.

### Key Features

The quality and characteristics of the different optical components and the combination are described in these terms:

- Cornea.
- Pupil.
- Lens.
- Accommodation.
- Scattering.
- Aberrations.
- Retina.
- Resolution and focal length.
- Depth of focus.
- Refractive errors.

### INTRODUCTION

Each optical component of the eye contributes to image formation on the retina and its brain interpretation. In order to discuss these components, we must first define the limits of normality considering the best image quality that can be produced by an emmetropic eye (an eye without refractive error). The determination of these limits is important, as they serve as guides for intervention on clinical practice. This chapter discusses individual optical variables that characterize the normal human eye as well as abnormal conditions of the refracting apparatus of the eye, also called ametropia.

### CORNEA

The cornea's anterior surface is approximately spherical, with a radius of curvature that is typically a bit less than 8 mm. This surface is responsible for about two-thirds of the eye's refractive power. Technology based in the Scheimpflug principle allows for the detailed analysis of each interface together with the local thickness in estimating the total corneal power for an individual eye before and after corneal surgery.<sup>1</sup> The corneal stroma must be transparent for high-quality image formation on the retina, yet the normal human cornea scatters 10% of the incident light.<sup>2</sup> By comparison, the corneal stroma of the eagle is almost as transparent as glass.<sup>3</sup> This factor (along with the larger pupil size and finer cone diameter) is why the resolution of the eagle eye is better than 120 cycles per degree, which is equivalent to a Snellen acuity of 20/5 (6/1.5).<sup>4</sup>

The aspherical shape of the cornea's anterior surface affects the quality of the retinal image. Normal corneas have a flatter periphery and steeper center, counteracting the effect of paraxial light that tends to bend more at peripheral areas. The "Q" factor, also named asphericity or eccentricity factor, quantifies this central-periphery flattening and averages  $-0.25$  in normal eyes. A more negative number means that this cornea is steeper than normal (i.e., central keratoconus), and less negative "Qs" are seen, for example, in postrefractive myopic procedures. Such knowledge was built into equipment for new refractive surgeries that allows for the control of final "Q" factor, aiming for better contrast definition after surgery.<sup>5</sup>

Corneal astigmatism is caused by this surface having different radii of curvature along different meridians (directions in the coronal plane). A

survey of normal eyes shows that almost every human eye has a baseline corneal astigmatism of at least  $0.25$ – $0.50$  D.<sup>6</sup> Spherical aberration is caused by the radius of curvature of the corneal surface changing (generally increasing) with distance from the center of the pupil to the pupillary margin. Several devices based on Placido's ring principle provide quantitative data on corneal aberrations.<sup>7</sup> The amount of spherical aberration contributed by the cornea varies with pupillary aperture and individual corneal shape. For a pupil 4 mm in diameter, spherical aberration varies from  $+0.21$  D to  $+1.62$  D, depending on the specific corneal form.<sup>8</sup>

### PUPIL

The iris expands or contracts to control the amount of light admitted to the eye. The pupil can range in diameter from 8 mm in very dim light down to about 1.5 mm under very bright conditions.<sup>9</sup> A strong association exists between visual acuity and pupillary diameter. For example, visual acuity has been shown to improve steadily as background illumination increases up to a value of  $3400$  cd/m<sup>2</sup>.<sup>10</sup> This improvement is due to blockage of paraxial aberrant rays and brain compensation for the resulting dimming of retinal illumination. To deliver more light (larger pupil) without aberration it is necessary to control the peripheral shape of the cornea.

Retinal image quality, as determined by optical aberrations such as spherical aberration, tends to improve with decreasing pupil diameter, because peripheral optical aberrations decrease with decreasing pupil size. On the other hand, retinal image quality is limited by diffraction, which tends to improve with increasing pupil diameter. For most eyes the best retinal images are obtained when the pupil diameter is about 2.4 mm, which is the diameter at which the effects of aberration and diffraction are balanced optimally. Thus the optimal pupillary size seems to be determined by several influences. In fact, Campbell and Gregory have shown that pupil size tends to be adjusted automatically to give optimal visual acuity over a wide range of luminance.<sup>11</sup>

### LENS

The crystalline lens, which has about one-third of the eye's refractive power, enables the eye to change focus. When the eye views nearby objects, the ciliary muscle changes the shape of the crystalline lens by making it more bulbous and, consequently, optically more powerful. The lens of a young adult can focus over a range greater than 10 D. Presbyopia, which begins at about 40 years of age (depending on the environmental factors such as temperature),<sup>12</sup> is the inability of the eye to focus (accommodate) due to hardening of the crystalline lens with age. Experiments that disrupt the hard collagen within the lens are ongoing and may provide new insights in presbyopia correction.<sup>13</sup> When the eye can no longer accommodate at the reading distance, positive spectacle lenses of about 1.5–3 D are prescribed to correct the difficulty.

The normal 20-year-old crystalline lens scatters about 20% of the incident light. The amount of scatter is more than double this in the normal 60-year-old lens.<sup>14</sup> Such scatter significantly diminishes contrast sensitivity.<sup>15</sup> Also, the normal 20-year-old lens absorbs about 30% of incident blue light. At age 60, this absorption increases to about 60% of the incident blue light.<sup>16</sup> The increase of blue light absorption with age results in subtly decreased color discrimination and decreased chromatic aberration. It is possible that this increased absorption helps to reduce the amount of UV light reaching the older retina, protecting it from oxidative damage, which is seen in age-related macular degeneration.

The variation in index of refraction of the crystalline lens (higher index in the nucleus, lower index in the cortex) is responsible for neutralization of a good part of the spherical aberration caused by the human cornea. A progression toward positive spherical aberration throughout life due to the

**Fig. 2.2.1 Spherical Aberrations Produced by Lenses of the Same Shape.** (A) A glass lens. (B) A fish lens. The variation in index of refraction is responsible for the elimination of spherical aberration in the fish lens. (Reproduced from Fernald RD. Vision and behavior in an African Cichlid fish. *Am Sci* 1984;72:58–65.)

**Fig. 2.2.2 Accommodation by von Helmholtz Model.** (Courtesy Francisco Irochima, MD.)

crystalline lens has been described.<sup>17</sup> Fig. 2.2.1 shows how this variation of index of refraction in the spherical fish lens almost eliminates its spherical aberration compared with a spherical glass lens.<sup>18</sup>

## ACCOMMODATION

In a convergent optical system, as an object approaches, its formed image moves away from its original position, that is, farther away from the lens. Accommodation is a complex mechanism involving sensory and neuromuscular phenomena by which the human eye, through contraction of the ciliary muscle, changes the optical power of the lens to assist the convergence of the image to the retina, adjusting the focus to different distances between the object of regard and the eye.

According to the von Helmholtz model (the most widely held theory), when the visual target approaches nearer to the eye, there is a stimulus to the contraction of the ciliary muscle that leads to a relaxation of the suspensory ligaments of the lens, increasing its anterior–posterior diameter, and a forward shift of the lens, and, consequently, its dioptric power<sup>19,20</sup> (Figs. 2.2.2 and 2.2.3). The opposite occurs when relaxation of this musculature occurs.

The precise details of the mechanism of accommodation remain unclear to this day. Discussion of the various hypotheses currently under investigation is beyond the scope of this chapter.

The ability of the lens to change its shape is called physical accommodation, whereas the contraction capacity of the ciliary muscle is called

**Fig. 2.2.3 Zonules and Lens Details as Described by von Helmholtz.** Contraction of ciliary muscle leading to relaxation of the zonules and accommodation. (Courtesy Francisco Irochima, MD.)

physiological accommodation. Both alter the refractive power of the system and can be measured. If the lens becomes stiffer and unsightly, unable to alter its shape, physical accommodation is impaired even with the strength of the preserved ciliary muscle. A similar process may occur with physiological accommodation if weakness of the ciliary muscle<sup>21</sup> exists.

## Range and Amplitude

The greatest distance an object can be clearly seen by the eye with relaxed accommodation is called the “far point.” The nearest point at which an object can be clearly seen is called the “near point,” which is the location of the focus obtained with maximum accommodation. The range of accommodation, by definition, is the distance between these two points. The amplitude, measured in diopters, refers to the refractometric difference between the eye in maximum relaxation and maximum accommodation.

- **Far point:** The greatest distance at which an object can be seen clearly in the absence of accommodation.
- **Near point:** The closest distance at which an object can be seen clearly when maximum accommodation is used.
- **Range of accommodation:** Distance between the far point and the near point.
- **Amplitude of accommodation:** Difference in dioptric power between the eye at rest and the fully accommodated eye.

The amplitude of accommodation can be measured directly by the method of spheres. In this method, we ask the patient to look at an object 40 cm away and change his/her need for accommodation with the addition of lenses. By adding negative lenses, the accommodation is stimulated until the image begins to blur. For example, suppose the patient accepts  $-2$  D with clear vision. As we add positive lenses, the accommodation will relax until the image begins to blur again. Suppose in this situation, the lens used was  $+3$  D. In this case the patient has a 5 D amplitude of accommodation.

Further information can be obtained with simple examination. Placing an object at the nearest point where the patient can obtain sharp vision will determine the near point. Moving away the object, we define the far point. In the case of a patient with 3 D of amplitude: If he or she is emmetropic, the far point will be in infinity and the near point will be to 33 cm. If the patient is a 3 D hyperope, the near point will be at infinity, because all the accommodation must be used to clarify the acuity at distance. If the patient has a myopia of 3 D, the near point will be 16.7 cm because the accommodation together with the refractive error amounts to a total of 6 D of refractive power.

In a hyperope, the accommodation necessary to see clearly at a distance is the same diopters of the magnitude of their hypermetropia. However, to see a near object 10 cm from the eye, as we saw before, 10 diopters (D) should be added to this value.

In hyperopia, there is *no* object distance for which a clear retinal image can be obtained without accommodation (or optical correction)—the optical apparatus of the eye has too little dioptric power at rest to focus an object on the retina. In this case we may define the far point of the eye as the (virtual) point, located *behind* the eye, which is imaged by the relaxed optics of the eye on the retina. Additional plus lens power, either from accommodation or supplied by a spectacle lens, is necessary to obtain a clear image.

For example, assuming a 4 D hyperope with amplitude of accommodation of 8 D, the (virtual) far point is at 25 cm behind the eye. With an accommodating effort of 4 D, the parallel rays from an object at infinity converge to the retina. Note that with an 8 D effort, this hyperope can converge divergent rays from a point 25 cm away from the eye. Assuming that this is the maximum available accommodation, by definition this is the near point (Fig. 2.2.4). It is important to note that this hyperope needs to accommodate between 4 D and 8 D to see objects ranging from infinitely distant to the near point. In other words, in some situations, the hyperope can have the same range as an emmetrope but the required amplitude of accommodation is necessarily greater, that is, the hyperope needs a greater accommodative effort. The prescription of lenses for this patient should take into account maintaining a more physiological accommodative effort. This process is discussed in the next chapter.

In myopes, the far point is at a finite distance in front of the eye. In a myopic eye that sees objects at most up to 20 cm distant from the eye, a myopia of  $1/0.2 = 5$  D exists. Remember that the accommodation of an eye when viewing an object at the far point is fully relaxed. If the near point is at 10 cm, the accommodation range will be  $\alpha = 20 - 10 = 10$  cm. As at this

point, as we saw before, the added refractive power of the system is 10 D. The amplitude of accommodation will be the difference of the power in the two points, that is,  $A = P - R = 10 - 5 = 5$  D. Notice that a 5 D myopic eye accommodates 5 D to focus an image at 10 cm. Therefore, although myopes cannot see objects at distance clearly, they have the advantage of being able to see objects at closer range with a smaller effort of accommodation (Fig. 2.2.5).

## SCATTERING

Another significant optical factor that degrades vision is intraocular light scatter. The mechanism of light scatter is different from the aberrations discussed earlier, each of which deviates the direction of light rays coming from points in object space to predictable and definite directions in image space. With light scattering, incoming light rays are deflected from their initial (i.e., prescattered) direction into random (postscattered) directions, which generally lie somewhere within a cone angle of approximately a degree or so. Therefore a dioptric value cannot be placed on the blur caused by light scatter. A glaring light worsens the effect of light scatter on vision. Thus a young, healthy tennis player may not see the ball when it is nearly in line with the sun. Light scattering is the mechanism associated with most cataracts and causes significant degradation of vision due to image blur, loss of contrast sensitivity, and veiling glare.

## ABERRATIONS

Aberrations are changes in image formation that do not occur in a classically paraxial system.<sup>22</sup> In other words, in specific situations, such as when light incidence occurs at an angle far above the reference axis of the system, no formation of an image exists at a single point. In practice, an optical system never makes a perfect point image and this does not depend only on the regularity of the surface. With the advent of wavefront aberrometry, several new types of aberrations—especially those of high orders—can be classified and today become major challenges for optical system manufacturers and refractive surgeons.

The aberrations are divided into monochromatic and chromatic. The monochromatic aberrations can be further subdivided into several types: astigmatism, defocus, tilt, spherical aberration, among others.

### Monochromatic Aberrations

Monochromatic aberrations of a geometrical nature are also called figure aberrations. In spherical aberration, for example, light rays that refract at the extreme periphery of a convergent lens have a different focus from those that enter the eye more centrally, better aligned with the optical axis. Thus between them, many of the rays will cross at intermediate points, degrading the nominal point image (see Fig. 2.2.1). A comet-like tail or directional flare appearing in the retinal image is a manifestation of another aberration called coma. This occurs due to the obliquity of the system, resulting from misalignment of the various refracting surfaces in the eye. A large amount of coma ( $0.3 \mu\text{m}$  of coma alone) may point to specific corneal diseases such as keratoconus or a decentered intraocular lens. Several other forms of monochromatic aberrations are induced by differences in the axial curvature of the lens and inclination of the light beams, among others.

### Chromatic Aberrations

Because the index of refraction of the ocular components of the eye varies with wavelength, colored objects located at the same distance from the eye are imaged at different distances with respect to the retina. This phenomenon is called axial chromatic aberration. In the human eye the magnitude of chromatic aberration is approximately 3 D.<sup>23</sup> However, significant colored fringes around objects generally are not seen because of the preferential spectral sensitivity of human photoreceptors. Studies have shown that humans are many times more sensitive to yellow-green light with a central wavelength at 560 nm than to red or blue light.<sup>8</sup> Amber spectacles used to enhance night vision partially block the blue light, lowering the effect of chromatic aberration.

The specific types of each monochromatic and chromatic aberration are discussed in Chapter 2.6.

## RETINA

An image may be considered as made up of an array of pointlike regions. When a picture on the video screen is viewed with a magnifying glass, these small regions, called *pixels*, are seen clearly. Technological evolution

**Fig. 2.2.4 A 4 D Hyperope Eye.** (A) The far point (FP) is at 1.24 mm behind the retina. (B) The image focus on retina after 4 D of accommodation. (C) The near point (25 cm) after maximum accommodation of 8 D. (Courtesy Francisco Irochima, MD.)

has produced screen resolution above the human vision threshold in the new generation of smartphones or monitors with so-called retina display. Likewise, the pixel elements comprising a retinal image are the cone and rod photoreceptors. It is the finite size of these photoreceptors that ultimately determines the eye's ability to resolve fine details.

The finest details in a retinal image can be resolved only within the foveal macular area. This elliptical zone of about 0.1 mm in maximal width (Fig. 2.2.6)<sup>24</sup> has an angular size of approximately  $0.3^\circ$  about the eye's visual axis. It contains about 30,000 tightly packed light-sensitive cones. The cones themselves have diameters of 1–2  $\mu\text{m}$  (a dimension comparable to 3–4 wavelengths of green light) and are separated by about 0.5  $\mu\text{m}$ .<sup>25</sup> Cone size is an important factor in determining the ultimate resolution of the human eye. No nerve fiber layer, ganglion cell layer, inner plexiform layer, or inner nuclear layer is present in much of the fovea, and in the very center of the fovea no outer nuclear layer is present. Only the so-called Henle's fiber layer, consisting of the axons between the cones and their synaptic pedicles, and the cones themselves are found.

Another important aspect of the cone receptors is their orientation. Each cone functions as a "light pipe" or a fiber optic that is directed to the second nodal point of the eye (Fig. 2.2.7). This orientation optimally receives the light that forms an image and, together with the black pigment epithelium of the retina, partially prevents this light from scattering to neighboring cones.<sup>26</sup> Müller cells may also be considered living optic fibers in the retina,<sup>27</sup> preventing light scatter.

Another retinal factor that helps to improve vision is the configuration of the foveal pit, which is a small concavity in the retina. This recessed shape acts as an antiglare device in which the walls of the depression prevent stray light within the internal globe of the eye from striking the cones at the center of the depression. Finally, the yellow macular pigment may be considered to act as a blue filter that limits chromatic aberration

and absorbs scattered light, which is predominantly of shorter wavelength (i.e., the blue end of the spectrum).

## RESOLUTION AND FOCAL LENGTH

A derivation of the theoretical diffraction-limited resolution of a normal emmetropic human eye must consider the eye's optimal pupil diameter, its focal length, which is associated with its axial length, and the anatomical size of the photoreceptors. A point object imaged by a diffraction-limited optical system has an angular diameter in radians (diameter at one-half the peak intensity of the Airy disc) given by Eq. 2.2.1.

$$\text{Angular diameter} = \frac{1.22 (\text{wavelength})}{\text{pupil diameter}} \quad \text{Equation 2.2.1}$$

In Eq. 2.2.1, let pupil diameter be 2.4 mm, which for a normal eye is the largest pupil diameter for which spherical aberration is insignificant, and let the wavelength be 0.00056 mm (yellow-green light) to find the diffraction-limited angular diameter = 0.00028 radians (or, equivalently, 0.98 minutes of arc). Note that this angular diameter matches the angular resolution of an eye with 20/20 Snellen acuity, because the black-on-white bands of the letter E on the 20/20 line of the Snellen chart are spaced 1 minute of arc apart.

The spatial diameter in millimeters of the diffraction-limited Airy disc on the retina is found by multiplying the angular diameter, given by Eq. 2.2.1, by the effective focal length of the eye.

$$\text{Spatial diameter} = (\text{angular diameter}) \times (\text{effective focal length}) \quad \text{Equation 2.2.2}$$

**Fig. 2.2.5 A Myopic Eye of 5 D.** (A) Far point is situated at 1.33 m in front of the retina. (B) At 20 cm distance, the image focus on retina without accommodation. (C) Maximum accommodation of 5 D and the near point at 10 cm. (Courtesy Francisco Irochima, MD.)

**Fig. 2.2.6 Retinal Mosaic (Rhesus Monkey) in an Area Adjacent to the Fovea.** The large circles are rods and the clusters of small circles are cones. This section gives a perspective of the different receptor sizes. (From Wassle H, Reiman HJ. The mosaic of nerve cells in mammalian retina. *Proc R Soc Lond B* 1978;200:441–61.)

Using the angular diameter found from Eq. 2.2.1 and a value of 17 mm for the eye's effective focal length (i.e., second nodal point to retina distance) in Eq. 2.2.2 results in the diffraction-limited spatial diameter = 0.0048 mm (i.e., 4.8  $\mu\text{m}$ ).

It is interesting to use our results to make a comparison with Kirschfield's estimate that about five receptors are needed to scan the Airy disc to obtain the maximal visual information available.<sup>28</sup> If we assume

**Fig. 2.2.7 Orientation of the Photoreceptors.** They all point toward the second nodal point of the eye. (Courtesy Francisco Irochima, MD.)

that the foveal cones are approximately 1.5  $\mu\text{m}$  in diameter and are separated by about 0.5  $\mu\text{m}$  of space, then the distance between neighboring cones is 2.0  $\mu\text{m}$ . We estimate the number of receptors covered by the Airy disc by calculating in Eq. 2.2.3 the ratio of the area of the Airy disc to the area occupied by a single cone.

$$\text{Number of cones covered by Airy disc} = \frac{(\text{spatial diameter of disc})^2}{(\text{distance between cones})^2}$$

**Equation 2.2.3**

Using Eq. 2.2.3 we find that approximately six receptors are covered by the Airy disc in close accord with Kirschfield's estimate of five. Thus given an eye with maximal sensitivity to yellow light and an optimal pupil size of 2.4 mm, we find that the human eye's 17 mm effective focal length and, correspondingly, its 24 mm axial length are properly sized to achieve optimal resolution for the cone sizes present. The higher resolution of the eagle's eye compared with the human's eye probably results from a larger pupil size-to-focal-length ratio, cones of smaller diameter, and a clearer cornea and lens.<sup>3</sup>

## REFRACTIVE ERRORS

In an emmetropic eye, parallel light rays that come from infinity, after refracting on the cornea and lens of an eye at rest, converge on the retina. Refractive errors, or ametropias, are anomalies of the optical state of the eye that cause imperfect focus on the retina, leading to a poor quality of the final image.

Refractive errors can occur for several reasons:

### *Change in Size or Position or Absence of Optical Elements*

A major cause of ametropia is a mismatch between the axial length and the refractive power of the optical elements of the eye, for example in an enlarged eye the image is formed in front of the retina—this is referred to as axial myopia. Similarly, on an eye with reduced anterior–posterior diameter, the image is formed behind the retina, referred to as axial hypermetropia (Figs. 2.2.8 and 2.2.9).

If the lens is positioned more anterior or posterior than the normal range, similar refractive errors occur. If the lens is displaced anteriorly, myopia results. Conversely, if the lens is displaced posteriorly, this causes hypermetropia. The lens may also be subluxated or tilted, causing astigmatism.

The absence of the lens, or aphakia, reduces the high power of convergence of the optical system, producing high hypermetropia.

### *Change in the Shape of Optical Elements*

Irregularities on the surface of the cornea can occur with the formation of images in two different planes, instead of a single point, causing astigmatism. If the curvature is regular but steep, it causes refractive myopia. If it's more flat, it causes refractive hyperopia. These types of ametropia are widely seen in clinical practice in various corneal diseases, such as keratoconus, marginal pellucid degeneration, and keratoglobus.

### *Change in Refractive Indexes*

The refractive power created at a tissue interface is proportional to the difference in the refractive indices of the two tissues. If, as a consequence of some pathology, the index of refraction of the aqueous humor increases, the negative power of the interface between the cornea and aqueous humor will be decreased, causing index myopia. Index hyperopia occurs if it is decreased. The opposite occurs with changes in the refractive index of the vitreous body. If the refractive index of the vitreous increases, becoming closer to that of the lens, light will be refracted less at the lens–vitreous interface, causing index hyperopia. Index myopia occurs if the refractive index of the vitreous is decreased. Such changes in the index of aqueous and vitreous are seldom observed (except following surgical procedures, which may temporarily replace these tissues with air or silicone oil). It is believed that during aging, with the formation of nuclear cataract, the lens nucleus increases its refractive index, producing mild myopia. Something similar happens with cortical cataract, which with aging approaches the index of refraction of the nucleus, causing mild hypermetropia. Such ametropic effects of lens aging are often the presenting signs of cataract formation and may be mistaken for “improvement” of presbyopia (“second sight”). Frequently, further lens changes eventually degrade image quality, necessitating cataract extraction surgery.

It is important to note that there often appears to be a coordination between the axial growth of the eye and the evolving refractive power of the anterior segment, so that the net refractive error is typically less severe than might be expected if these structures developed independently—a phenomenon referred to as “emmetropization.” Thus one cannot accurately predict the refractive error simply knowing only the axial length or refractive power of the eye in isolation.<sup>21</sup>

**Fig. 2.2.8 Ametropias.** (A) Emmetropic eye. (B) Myopic eye. (C) Hyperopic eye. (Courtesy Francisco Irochima, MD.)

## Myopia

Myopia is the condition in which parallel light rays from infinity, as they refract on cornea and lens, converge at a focus in front of the retina. There the light rays cross, forming a “blur circle” for each point of the source object. The image that projects itself into the retina thus corresponds to the sum of the blur circles, causing poor image quality.

Only diverging rays from nearby objects naturally converge to a sharp focus on a myopic eye's retina. Due to the high positive power, parallel rays from infinity or convergent rays tend to converge until they reach a focus in front of a retinal point. Therefore it is common to see a myopic person bringing objects near the eye to improve the quality of the image, so that the rays of light leaving the object diverge. Another method of correction is the prescription of negative lenses, which cause the parallel rays from an object at infinity to diverge as they enter the eye, allowing a sharp focus on the retina.

In myopia the distance from the nodal point (optic center) to the retina is greater than is found in a typical “normal” eye, and, therefore, the projected image will be larger than normal, unlike hyperopes, in whom the optics project a smaller image.

The far point in myopia is at a finite distance in front of the eye. As seen previously, the emmetropic eye has the far point at infinity. In myopes, the distance to the far point is inversely proportional to the ametropia. For example, a myope of 0.25 D has its far point in  $1/0.25 = 4$  m.

On the other hand, the myope needs less accommodative effort for near vision. Thus the accommodation, if used in its entirety, can maintain an object in good definition even at small distances, smaller than those accepted by the emmetrope. For example, a 4 D myopic patient who

**Fig. 2.2.9 Refractive Errors.** (A) Emmetropic eye. (B) Axial myopia. (C) Axial hyperopia. (D) Index myopia (nuclear cataract). (E) Aphakia. (Courtesy Francisco Irochima, MD.)

accommodates up to 8 D will have its far point at 25 cm, that is, without accommodation, he or she will see an object clearly at this distance, acting like an emmetropic accommodating 4 D. His or her near point will be  $100 / (4 + 8) = 8.3$  cm, because at this distance the eye resembles that of an emmetropic accommodating 12 D but with less effort.

## Hypermetropia

Hypermetropia, or hyperopia, is the condition in which parallel light rays from infinity converge on a focus behind the retina after refracting on the cornea and lens. What is projected into the retina thus corresponds to blur circles formed before the light rays converge to a point, causing poor image quality.

Contrary to common belief, there are more hyperopes in the world population than myopes. However, many do not manifest it until the age of 40, as their refractive errors are typically neutralized by accommodation without spectacle correction. After age 40 years, the amplitude of accommodation decreases, generating presbyopia, which will be further discussed later.

At birth the human eye usually has a hyperopia of + 2.25 D that increases and peaks at approximately 8 years of age. After this age, the eye will progressively become more myopic, reaching emmetropia in adulthood.<sup>29</sup> Growth of the eye during development is a complex process, usually accompanied by changes in corneal curvature and in the dioptric power of the lens. Hyperopia occurs when there is an imbalance between these mechanisms, such as the axial diameter decreasing relative to the refractive power of the other elements of the eye, as discussed previously. Generally the shortening of the eye does not exceed 2 mm. Each millimeter of shortening of the diameter corresponds to about 3 D of refractive error. Therefore, excluding pathological abnormalities such as microphthalmia, few hyperopic eyes exceed a refractive error of 6 D.<sup>21</sup>

In hyperopia the far point is a virtual point located behind the retina, because only converging rays can focus on the retina of an uncorrected

hyperope (Fig. 2.2.10). Because not enough convergence exists to see objects at a distance, positive dioptric power must be added, which is usually done through prescription of converging lenses, artificial corneal steeping by refractive surgery, or by the physiological mechanism of accommodation itself. For eyes with the same amplitude of accommodation, the hyperope has its near point at a greater distance, because part of its accommodation is already used to converge parallel rays from infinitely distant sources, unlike in myopia (Fig. 2.2.11).

Hyperopia can be divided into latent and manifest hyperopia. Ideally, a clinical refraction is performed with the eye in a state of complete relaxation of accommodation. Such a state is artificially induced by cycloplegic eyedrops and does not occur in an eye in its natural state. Thus, if the ametropia measured during cycloplegia were used as the prescribed correction, this would likely be uncomfortable and not generate the best quality of vision for the patient, who would probably continue to exhibit some degree of accommodative tone after the cycloplegia wears off.

Indeed, the normal tonus of the ciliary body obscures a latent hyperopia, that is, an accommodation that is present even with the eye adjusted to fix a distant image, using the least possible accommodative effort. Latent hyperopia usually is around 1 D, and its understanding is important in daily practice for prescribing a more physiological refraction to the patient.<sup>30</sup>

The manifest hyperopia is the amount of diopter power required to reach emmetropia after minimal (latent) accommodation. Taking into account that in that state, there is still available some power of accommodation, one may subdivide the manifest hyperopia in two facultative and absolute hypermetropia. The facultative is that part of manifest hyperopia that can be overcome by accommodation. Thus the absolute is the remaining refraction error after maximum accommodative effort (Fig. 2.2.12).

## Astigmatism

Astigmatism is a condition in which the light rays, after refracting, do not converge to a single point. Due to variations in the curvatures of the cornea

**Fig. 2.2.10** Far point on (A) emmetropic eye, (B) myopic eye, (C) hyperopic eye. (FP) Far point. (Courtesy Francisco Irochima, MD.)

or the lens in different axes, instead of focusing the light from a point source to a single point, the image consists of two lines, separated from each other.

When the light from the main meridians that focus on the system in this optical condition are at right angles to each other, this is referred to as regular astigmatism. If, however, these principal meridians form a right angle but not oriented horizontally and vertically (at  $90^\circ$  and  $180^\circ$ ), the condition is described as oblique astigmatism. If the cornea or lens are so irregular that they do not form well-defined meridians, the condition is described as irregular astigmatism.

In regular astigmatism, depending on where the two lines focus, one may specify further subtypes. If both are in front of the retina, the refractive state is compound myopic astigmatism. Similarly, if both are behind, a compound hypermetropic astigmatism results. If one line focuses on the retina but the other line is in front or behind, one obtains a simple myopic or simple hypermetropic astigmatism, respectively. If one line focuses in front and the other behind the retina, the condition is called mixed astigmatism (Fig. 2.2.13).

In the space between the two focal lines, the light rays determine a characteristic geometrical figure called the conoid of Sturm (Fig. 2.2.14). The spacing of these focal lines (i.e., the size of the conoid) is a measure of astigmatism, and its correction is based on merging the focal lines into one, collapsing the conoid of Sturm to a single point. If the error is not corrected, the projected image on the retina within this space will form circles, ellipses, or lines, but never a single point, causing a blurred image. Note, however, that cylindrical lenses apply their power under the rays to  $90^\circ$  from the plane of their axis, not altering the rays on their own axis. Thus correction with cylindrical lenses can only be done in regular astigmatism.

In the center of the conoid, there is a region where the image is closest to forming a point, a circular region (due to the pupil shape) called the circle of least confusion. The circle of least confusion is the “best” image after light passes through an optical system with spherocylindrical power

(an eye with astigmatism). Thus with the spherical equivalent of optical correction, which places this circle on the retina, we will have the best image that can be obtained by correcting an astigmatism with only spherical lenses.

Although no eye is perfectly free from astigmatism, in practice it is necessary to correct astigmatic refractive errors only when patients experience symptoms such as decreased visual acuity or eye fatigue from constantly adjusting accommodation to optimize the seeing between the two focal lines.

## Presbyopia

As seen earlier, manifest hyperopia has its facultative and absolute component. The facultative component, which can be compensated by accommodation, decreases progressively with age, so the absolute hyperopia will eventually become evident in those hyperopes that did not exhibit this component earlier in life (when hyperopia is totally neutralized by accommodation). In such symptomatic patients, absolute hyperopia increases and symptoms become more evident around the age of 40, requiring greater optical correction. Myopes, as they have the near point at a shorter distance, usually have a “natural protection” against presbyopia. Myopes with small refractive errors, however, will also require positive diopter power for near objects after a more significant progression of presbyopia.

Fisher<sup>31</sup> published an important paper in 1988 breaking previous paradigms, such as those published by von Helmholtz<sup>32</sup> that presbyopia was due to lenticular sclerosis and by Donders,<sup>33</sup> who argued that the loss of strength of the contraction of the ciliary muscle was the main cause.

In his article, Fisher states that at the beginning of presbyopia, there is in fact hypertrophy of the ciliary muscle as a compensatory form to the greater difficulty of lenticular diameter alteration. This difficulty, however, was not due to sclerosis but rather to the stiffening of the lens capsule associated with changes in the zonule structure, which became more compact.<sup>31</sup>

**Fig. 2.2.15** Accommodation (D – diopters) X Age (years), according to Duane.<sup>34</sup> (A) Minimum values, (B) medium values, (C) maximum values. (Courtesy Francisco Irochima, MD.)

Later, it was proved that the role of the stiffening of the crystalline nucleus itself would also play a part in the phenomenon. Thus aging would be associated with complex physical and optical changes in the crystalline structure responsible for changes not only limited to loss of accommodation and cataract.<sup>30</sup>

With the loss of amplitude of accommodation during aging, therefore, the near point gradually recedes, making it harder to see near objects with clarity. This phenomenon should not be seen as pathological, but rather as a normal—indeed inevitable—consequence of aging.

Note that at age 45 the range of accommodation is around 2 D. In practice, this does not mean that the patient will be able to routinely exert this

entire accommodative power, because maximal prolonged accommodative effort is usually only one-third to one-half the total amplitude. Thus in a comfortable and tolerable way, the routinely available accommodation at that age usually is less than 1 D, which means that optical corrections will usually be necessary for near vision in a previously emmetropic patient (Fig. 2.2.15).

The treatment of presbyopia is performed with the use of convex lenses, bringing the near point to a region of comfortable working distance that is compatible with the patient's needs. With advancing age, the depth of focus through a presbyopic correction will decrease, potentially creating a gap between the closest focus with the distance correction, and the most distant focus available through the reading correction. If this is bothersome, the patient may be helped by a prescription for trifocals, with an intermediate presbyopic correction zone, or progressive lenses, which provide a continuous transition between distance and near corrections.

# Clinical Refraction

Albert Wu

## 2.3

**Definition:** The neutralization of an individual's refractive error using a variety of tests in which the patient's responses determine the lens power that best produces a sharply focused image on the retina.

### Key Features

- The selection of a prescription for corrective lenses that balances optical clarity with other important physical and psychological factors, such as equality of magnification, single vision, and comfort.
- The determination of the most appropriate form of optical correction based on the patient's visual needs and on environmental factors.

### INTRODUCTION

Many people equate an eye examination with a refraction test for glasses. The confusion is understandable because for the vast majority, especially those in the preretirement age group, eyeglasses or contact lenses resolve the main complaints they have about their eyes. Also, refraction is almost always part of a comprehensive eye examination, not only to provide a prescription for corrective lenses but also to determine the best acuity that an eye can achieve.

Refraction is only one of the many methods used to determine the function and health of the visual system. Because of the value of the results, it is important to develop an efficient and accurate basic refractive technique that can be modified when unusual variations present themselves.

Although often relegated as a purely technical task in the spectrum of high-technology examination and treatment procedures that characterize contemporary ophthalmic practice, refraction provides relief for one of the world's most common physical defects. An understanding of the concepts used to identify and measure refractive errors is the basis for prescribing individual corrections that offer patients improved quality of life.

### HISTORY

Spectacles were first described during the Middle Ages. In 1266 Roger Bacon magnified print in a book using a segment of a glass sphere. A painting completed in 1352 shows a prelate wearing lenses in a mounting. In the late fifteenth century, merchants sold spectacles to buyers who chose them on the basis of their own judgment of how vision improved. As the trade of lens-making proliferated throughout Europe, it became organized into a guild. Although cylindrical lenses had been manufactured since 1827, it was not until Donders published his methods of refraction that correcting astigmatism became an exact science. In 1893 when American Optical developed the trial case of lenses, opticians—rather than spectacle peddlers—became the primary providers of eye examinations.<sup>1</sup> Although instrument-makers have dramatically improved the ability of examiners to provide accurate and repeatable lens prescriptions, most subjective techniques still rely on a comparison of views through different lenses.

### VISUAL ACUITY

The idea that the minimal separation between two point sources of light was a measure of vision dates back to Hooke in 1679, when he noted, "tis hardly possible for any animal eye well to distinguish an angle much smaller than that of a minute: and where two objects are not farther distant than a minute, if they are bright objects, they coalesce and appear as one."<sup>2</sup> In the early nineteenth century, Purkinje and Young used letters of various sizes for "judging the extent of the power of distinguishing objects too near or too remote for perfect vision." Finally, in 1863, Professor Hermann Snellen of Utrecht developed his classic test letters. He quantitated the lines by comparison of the visual acuity of a patient with that of his assistant, who had perfect vision. Thus 20/200 (6/60) vision meant that the patient could see at 20 ft (6 m) what Snellen's assistant could see at 200 ft (60 m).<sup>3</sup>

The essence of correct identification of the letters on the Snellen chart is to see the clear spaces between the black elements of the letter. Thus in Fig. 2.3.1, the angular spacing between the bars of the C is 1 minute for the

**Fig. 2.3.1 Spacing of Gap in the Letter "C."** This letter is used to determine the minimal separable spacing or resolution of the eye at the retina. The gap in the letter C subtending 1 minute, when imaged on the retina, has a dimension (Y) representing the resolution of the eye where  $\tan(1 \text{ minute}) = Y/0.67$  (with Y in inches); therefore,  $Y = 0.00019$  inches (or 4.8 m). The overall size of the letter is  $X = 0.349$  inches, and the gap dimension is 0.070 inches (see text).

20/20 (6/6) letter. The entire letter has an angular height of 5 minutes. To calculate the height,  $x$ , of a 20/20 (6/6) letter, use Eq. 2.3.1.

$$\tan(5 \text{ minutes}) = \frac{x \text{ feet}}{20}$$

Equation 2.3.1

From Eq. 2.3.1,  $x = 0.0291 \text{ ft}$  (0.349 in). In like manner, the 20/200 (6/60) letter is 10 times taller, or 3.49 in (8.87 cm) high.

Testing Distance

The Snellen acuity test traditionally is done at a distance of 20 feet (6 m). At this distance, very little accommodation is required by the patient. For hospital patients, testing must often be carried out in a smaller room. If the doctor stands at the foot of the bed and the patient sits propped up at the head of the bed, the distance between them is about 5 feet (1.5 m). Thus the classic Snellen chart, with its conventional notations, may be used if the chart is reduced to one-fourth its original size. Admittedly, a test at 5 ft (1.5 m) requires the emmetropic patient to accommodate 0.67 diopters (D).

Other Considerations

Over the years, it has become apparent that projection of the Snellen chart onto a screen in a darkened examination room does not give an accurate replication of “everyday” visual function. For example, the high contrast black-on-white letters do not represent the contrast of most objects seen in everyday life. The dark examination room, which is devoid of glare sources, also is not representative of most daytime visual tasks.

As the projector bulb ages or collects dirt, and as the projection lens becomes dusty, the contrast of the letters projected on the chart decreases. Thus a change in readings between patient visits may not always arise from a significant change in the visual status of the patient. At present, British standards require 480 to 600 lux to illuminate distant wall charts and 1200 lux to illuminate projected charts.<sup>4</sup>

As the letters become smaller on the Snellen chart, the number of letters per line increases. Thus one error per line means a different degree of impairment for each line. It is necessary, therefore, to establish criteria by which it can be agreed that a patient has seen the line. Some clinicians credit a patient if more than one-half the letters are identified correctly. Others require identification of all the letters before credit is given. Also remember that no orderly progression of size change exists from line to line. Thus a two-line change on the Snellen chart going from the 20/200 (6/60) line to the 20/80 (6/24) line represents an improvement of visual acuity by a factor of 2.5, whereas a two-line change going from the 20/30 (6/9) line to the 20/20 (6/6) line represents an improvement by only a factor of 1.5.

Another problem is that the identification of different letters of the same size has been shown to vary in difficulty. Thus A and L are easier to identify than E. The Bailey–Lovie chart (Fig. 2.3.2), designed by two Australian optometrists<sup>5</sup> and modified by Ferris et al.<sup>6</sup> in 1982, uses 10 letters of similar difficulty with five different letters per line and has uniform proportional size change between neighboring lines. Another approach is

to use the Landolt ring test in which circles of decreasing size, each with an open gap, are used in successive lines, with the orientation of the gaps in the circles randomly changing.

The 20/20 (6/6) Snellen line represents the ability to resolve 1 minute of arc, which is close to the theoretical diffraction limit, but the occasional patient can see the 20/15 (6/4.5) or, rarely, 20/10 (6/3) line. Four explanations suggest themselves. First, some individuals may have cone outer segment diameters of less than 1.5  $\mu\text{m}$ , which would give a finer-grain mosaic having cone separations of less than 1 minute of arc. Second, longer eyes provide slightly magnified retinal images, thereby tending to yield better acuities. Third, some eyes may have less aberration than others, which would allow them to function optimally with larger pupils having, consequently, better diffraction-limited performance. Finally, our experience with a small aperture corneal inlay has taught us that brain processing cancels much of the diffraction noise for apertures between 1.5 mm to 2.0 mm (US PATENT # 4955904, Atebara, Miller. US PATENT #5245367, Miller/Meshel. US PATENT #6899424, Miller, Blanco).

Contrast Sensitivity

Visual acuity testing is relatively inexpensive, takes little time to perform, and describes visual function with one notation, such as 20/40 (6/12). Best of all, for more than 150 years it has provided an end point for the correction of a patient’s refractive error. Yet contrast sensitivity testing, a time-consuming test born in the laboratory of the visual physiologist and described by a graph rather than a simple notation, has become a popular clinical test recently. It describes a number of subtle alterations of vision not accounted for by the visual acuity test. Thus it more accurately quantifies the loss of vision in cataracts, corneal edema, neuro-ophthalmic diseases, and certain retinal diseases. Although these advantages have been known for a long time, the recent enhanced popularity has arisen because of patients with cataracts. As lifespan increases, more patients who have cataracts request medical help. Very often, their complaints of objects that appear faded or objects that are more difficult to see in bright light are not described accurately by their Snellen acuity scores. Contrast sensitivity tests and glare sensitivity tests do quantitate many of these complaints.

Contrast sensitivity testing is similar to Snellen visual acuity testing in that it tests using several different sized letters or grid patterns. However, it is different from visual acuity testing because the letters (or grid patterns) are displayed in six or more shades of gray instead of the standard black letters of the Snellen chart. Thus contrast sensitivity testing reports show a contrast threshold (i.e., lightest shade of gray just perceived) for each of several letter (or grid pattern) sizes.

Contrast

The components of a conventional newspaper photo consist of various regions associated with the scene where each region is filled in with a definite density of black dots depicting that region’s contrast or level of gray. Such newspaper photos may have over 100 half-tone levels (i.e., densities of black dots) to represent the different contrast levels in the scene.

Whereas a black letter on a white background is a scene of high contrast, a child crossing the road at dusk and a car looming in a fog are scenes of low contrast. The contrast of a target on a background is defined by Eq. 2.3.2.

$$\text{contrast} = \frac{\text{target luminance} - \text{background luminance}}{\text{target luminance} + \text{background luminance}}$$

Equation 2.3.2

As an example, suppose a photometer measures the luminance of a target at 100 units of light and the luminance of the background at 50 units of light. Substitution into Eq. 2.3.2 gives Eq. 2.3.3.

$$\text{contrast} = \frac{100 - 50}{100 + 50} = 0.33 \text{ (or 33\%)}$$

Equation 2.3.3

Suppose the contrast of a target of a certain size is 0.33, which also may represent a particular older patient’s threshold, which means that this patient cannot detect similar-sized targets of lower contrast. The older patient’s contrast sensitivity (CS) is the reciprocal of the contrast, namely  $CS = 3.0$ . On the other hand, a young, healthy subject viewing a target of the same size may have a contrast threshold of 0.01 with a corresponding  $CS = 100$ . Occasionally subjects (for certain-size targets) have even better contrast thresholds. A subject could have a contrast threshold of 0.003, which converts into a CS of 333. In the visual psychology literature, CS often is described in logarithmic terms. For example, associated with CS

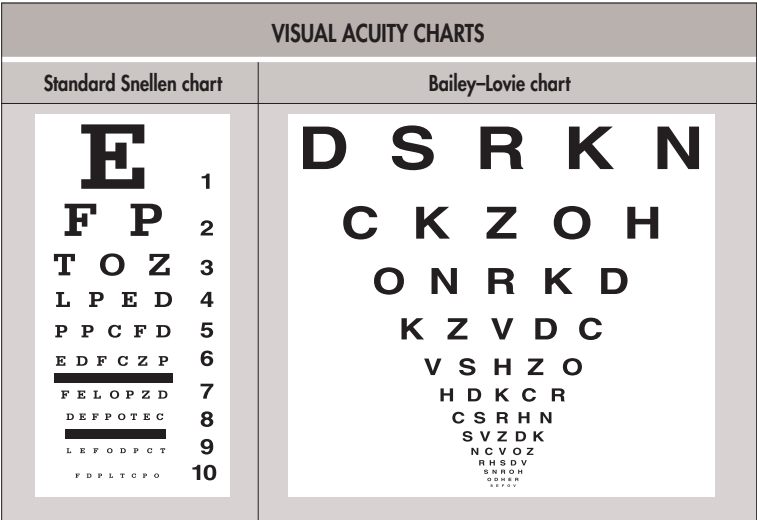

Fig. 2.3.2 Visual Acuity Charts. Standard Snellen and Bailey–Lovie charts.

= 10 is  $\log(\text{CS}) = 1$ , with  $\text{CS} = 100$  is  $\log(\text{CS}) = 2$ , and with  $\text{CS} = 1000$  is  $\log(\text{CS}) = 3$ , and so on.

### Targets

Both the visual scientist and the optical engineer use a series of alternating black and white bars as targets. The optical engineer describes the fineness of a target by the number of line pairs per millimeter (a line pair consists of a dark bar with a white space next to it). The higher the number of line pairs per millimeter, the finer is the target. For example, about 82 line pairs per millimeter imaged on the retina of an eye with a focal length of 21 mm is equivalent to a periodic black–white target in object space, where the white space between two black spaces subtends approximately a minute of arc (like the letter E of the Snellen chart viewed at 20 ft). Equivalently, with a Snellen chart viewed at 20 ft, 109 line pairs per millimeter on the retina is equivalent to the 20/15 (6/4.5) letters.

The vision scientist generally describes a periodic bar pattern in terms of its spatial frequency as perceived at the test distance—the units are cycles per degree (cpd). A cycle is a black bar and a white space. To convert Snellen units into cpd at the 20 ft (6 m) testing distance, the Snellen denominator is divided into 600 (180). For example, 20/20 (6/6) converts into 30 cpd. Likewise, 20/200 (6/60) converts into 3 cpd.

### Sine Waves

So far, targets have been described as high-contrast dark bars of different spatial frequency against a white background. These also are known as square waves or Foucault gratings. However, in optics very few images can be described as perfect square waves with perfectly sharp edges. Diffraction tends to make most edges slightly fuzzy, as do spherical aberration and oblique astigmatism, particularly in the case of the optics of the eye. If the light intensity is plotted across a strongly blurred image of a Foucault grating, a sine wave pattern results. Sine wave patterns have great appeal because they can be considered the essential elements from which any pattern can be constructed. The mathematician can break down any alternating pattern, be it an electrocardiogram or a trumpet's sound wave, into a unique sum of sine waves. This mathematical decomposition of patterns into sinusoidal components is known as a Fourier transformation. Fourier's theorem describes the way that any pattern may be written as a sum of sine waves that have various spatial frequencies, amplitudes, and phases.

Also, it is thought that the visual system of the brain may operate by breaking down observed patterns and scenes into sine waves of different frequencies. The brain then adds them up again to produce the mental impression of a complete picture. Fourier transformations may be the method the visual system uses to encode and record retinal images. It has been shown that different cells or “channels” occur in the retina, lateral geniculate body, and cortex that selectively carry different spatial frequencies.<sup>7</sup> So far, six to eight channels have been identified. It also has been shown that all channels respond to contrast—the cortex shows a linear relationship between the amplitude of the neuronal discharge and the logarithm of the grating contrast. Consequently, many contrast sensitivity tests are based on sine wave patterns rather than square wave patterns.

### Recording Contrast Sensitivity

Fig. 2.3.3 shows a number of functions, including the contrast sensitivity testing function for a normal subject. The shape of the human eye's contrast sensitivity function is different from that of an inanimate optical imaging systems in which the function generally decreases continuously from very low to very high spatial frequencies. For the normal human eye, the contrast sensitivity generally increases from very low frequencies to about 6 cpd and then decreases with increasing frequency beyond 6 cpd. The decrease of the contrast sensitivity with frequency above 6 cpd is due to the influence of diffraction and aberrations, which make the detection of finer details more difficult. The increase of the contrast sensitivity with frequency up to 6 cpd is due to the retina–brain processing system, which is programmed to enhance our contrast sensitivity in the range of 2 to 6 cpd. Receptor fields, on–off systems, and lateral inhibition are the well-known physiological mechanisms that influence the different spatial frequency channels and are responsible for such enhancement. In Fig. 2.3.3, the plot labeled retinal testing function (RTF) represents the retinal–neural system's contrast sensitivity performance.<sup>8–10</sup> A striking proof of brain enhancement of contrast is given in Fig. 2.3.4.

Also shown in Fig. 2.3.3 is the plot labeled modulation transfer function (MTF), which represents the sinusoidal components of the object-to-image transfer function for the purely optical portion of the visual system (cornea, lens).<sup>11</sup> The MTF is described more completely in the next section. A significant mathematical relationship exists among the three functions,

**Fig. 2.3.3 Contrast Functions.** The human eye's contrast sensitivity (CS) function is the product of the contrast transfer function of the purely optical contribution, called the modulation transfer function (MTF), and the contrast sensitivity function of the purely neuroretinal contribution, called the retinal testing function (RTF). The MTF is magnified 10× in the graph. (Redrawn from Mainster MA. Contemporary optics and ocular pathology. Surv Ophthalmol 1978;23:135–42.)

**Fig. 2.3.4 Effect of Brain's Contrast Enhancement Function.** One gray circle is seen against a black background and one against a white background. The brain's contrast enhancement function makes the gray look lighter against the dark background and darker against the light background.

which is expressed by Eq. 2.3.4, the so-called Campbell–Green relation,<sup>11</sup> and is illustrated in Fig. 2.3.3. The Campbell–Green relation has been demonstrated in clinical studies.<sup>12</sup>

$$\text{CS} = \text{RTF} \times \text{MTF} \text{ for all frequencies} \quad \text{Equation 2.3.4}$$

Differences in the contrast sensitivity function are expected among different subject groups. For example, contrast sensitivity decreases with age, for which two factors appear to be responsible. First, the normal crystalline lens scatters more light with increasing age,<sup>13</sup> which thus blurs the edges of targets and degrades the contrast. Second, the retina–brain processing system itself loses its ability to enhance contrast with increasing age.

The contrast sensitivity function also is an accurate method by which to follow certain disease states. For example, the contrast sensitivity function of a patient who has a cataract is diminished, as it is in another light-scattering lesion, corneal edema. Because the contrast sensitivity function is dependent on central nervous system processing, it is not surprising that conditions such as optic neuritis and pituitary tumors also characteristically have diminished contrast sensitivity functions.

The contrast sensitivity of patients also decreases as the illumination decreases.<sup>14</sup> Thus contrast sensitivity for a spatial frequency of 3 cpd typically drops from 300 to 150 to 10 as the retinal luminance drops from 9 trolands to 0.09 trolands to 0.0009 trolands. (The troland is a psychophysical unit. One troland is the retinal luminance produced by the image of an object, the luminance of which is 1 lumen/m<sup>2</sup> (1 lux) for an area of

**Fig. 2.3.5 An Uncorrected Astigmatic Eye With the Circle of Least Confusion on the Retina.** The horizontal and vertical focal lines are dioptrically equal in front of and behind the retina.

the entrance pupil of 1 mm<sup>2</sup>.) Therefore, when careful contrast sensitivity function comparisons are made, the illuminance of the test targets must be kept at the recommended value.

## SPHERICAL EQUIVALENT

There are three basic components in the specification of a spectacle lens: the spherical power, the astigmatic cylinder axis, and the cylinder power. An accurate determination of the spherical component is predicated on having fully corrected the astigmatic error to ensure that a point focus is obtained with the final correcting lens. Therefore subjective examinations proceed in that order. In eyes with astigmatism, each of the principal meridians produces a linear image at its focal distance. In the space between foci—the interval of Sturm—the image has a progressive change in its elliptic profile. At the focal distance of the dioptric average of the two principal powers, the image is round and is called the circle of least confusion. In an eye uncorrected for astigmatism, the best acuity occurs when the circle of least confusion falls on the retina (Fig. 2.3.5). At all other points within the astigmatic pencil, the image is distorted along the principal meridians whereby each point source produces an oval image.<sup>3</sup> The oval images of two or more adjacent point objects overlap along one of the principal meridians and appear darker along their long axes. Some refractive techniques use this effect to neutralize the astigmatic focus subjectively.

Spherical equivalent is an important optical concept that is applicable in the dispensing of contact lenses and glasses. It is defined as the spherical power whose focal point coincides with the circle of least confusion, where one would see minimal blurring in their vision. To calculate the spherical equivalent, disregard the axis and add half the cylinder power to the sphere power. This is the algebraic sum of the value sphere and half the cylinder value, representing the average of the two powers that make up spherocylinder.

A plus cylinder example:

$$+2.00 + 3.00 \times 120$$

The spherical equivalent is:

$$+2.00 + (+3.00/2) = +3.50$$

A minus cylinder example:

$$+2.00 - 3.00 \times 120$$

The spherical equivalent is:

$$+2.00 + (-3.00/2) = +0.50$$

Practically speaking, the spherical equivalent is useful for prescribing a spherical contact lens to a patient with a low level of astigmatism. It also is useful when prescribing astigmatic contact lens to an individual with high astigmatism beyond the maximum cylinder correction of  $-2.75$  commonly offered by many contact lens companies. As a result, one might prescribe the lesser amount of astigmatism and correct the spherical power based on the spherical equivalent. Another similar use of spherical equivalent would be when prescribing glasses to a patient with high astigmatism and reducing the full cylinder correction to help the patient adjust to their prescription.

## DETECTING ASTIGMATISM

One of the most common reasons that patients seek eye care is to obtain correction of their refractive error. However, refraction is also a diagnostic tool used to differentiate decreased acuity caused by uncorrected or incompletely corrected refractive error from blurred vision related to eye disease.

In most cases the final determination of the refractive correction is based on the patient's appreciation of the lens power that provides the clearest vision at the desired viewing distance. This procedure, subjective refraction, is a time-honored combination of the technical skill required to select a lens that produces a sharply focused image on the retina tempered with the fine art of determining the best overall correction incorporating other factors such as the balance between the two eyes, the patient's visual needs, the patient's age, and the rate of change of the refractive error. The concepts and procedures described here refer to neutralization of the refractive error with spectacles, but most of these principles and techniques also apply to correction using contact lenses.

## Utility of the Test

Subjective refraction is usually performed after an in-depth history has been obtained, which includes ascertaining that clear vision has been achieved previously in both eyes, describing visual symptoms and any relief provided with the current correction, and specific visual requirements related to work and avocations. It should be performed before any other test that might alter the patient's responses because of physical changes to the eye, such as Goldmann tonometry and gonioscopy. Any examination procedure that uses bright lights, such as ophthalmoscopy or slit-lamp evaluation, can produce a photostress response. Refraction should be done either before these tests are performed or after an appropriate recovery period.

## Procedure

Although a totally subjective test is possible, most examiners use a baseline starting point, such as an evaluation of the patient's previous

## THE PRINCIPAL MERIDIANS OF THE CLOCK CHART

**Fig. 2.3.6 The Principal Meridians of the Clock Chart.** (A) As seen by an eye with uncorrected astigmatism in which each image appears as a vertical oval. The overlapping ovals make the vertical line darker. (B) The same eye when the correct amount of cylinder is in place and the fogging lens has not been removed. Each image appears as a blurred circle so that all the lines appear equally dark. (C) The same eye with the full spherocylindrical correction in place. Each image appears as a sharp point, giving an even, well-focused appearance to the chart.

eyeglasses, retinoscopy, or the results of an automated refraction, which they then refine to meet the patient's requirements. In general, the goal is to determine the maximum plus-lens (or minimal minus-lens) power correction that provides clear far vision while minimally exerting accommodation, and a near correction that provides clear vision at the desired distances. Many methods have been developed to determine the "best" correction, any of which an adept refractionist can call on to resolve a specific refractive quandary. For the purposes of this chapter, only the most widely accepted methods are described.

## Instrumentation

As with most healthcare procedures, many levels of sophistication in the instruments are available to perform this technique. They range from highly automated scanners and analyzers that provide an objective measure of the eye's refractive error in seconds to the centuries-old method of placing loose lenses by hand into a trial frame worn by the patient. Each method has its proponents and in particular situations, each method has its advantages.

Automated refractors analyze the focal power of emitted light from the eye and convert it into a dioptric correction. They are very fast, require minimum skill levels to operate, and are fairly accurate. They also are very expensive. Certain high-end models have subjective refraction capability so that the correction can be refined in the instrument. Portable and hand-held automated refractors now are available.

Most practitioners rely on the manually operated refractor or phoropter that contains a battery of lenses arranged in geared wheels that can be positioned in front of the patient's eyes. The lenses can be changed quickly to provide a wide array of plus and minus spherical lenses as well as a range of cylindrical lenses, available in either minus cylinder and plus cylinder configurations, that can be rotated to the appropriate axis.

A trial frame can be used to mount loose trial lenses in front of the patient's eyes. Trial frame refraction is a time-consuming procedure, and because of the thickness of individual lenses, especially at stronger powers, a power shift is induced when several lenses are stacked together. This error can be minimized by placing the strongest spherical lens in the rear well closest to the patient's eye. A variation of this technique is to use a clip-on trial lens holder, which can be mounted on the patient's current glasses or on a "loaner" pair of glasses made up in a spherical power close to the patient's required correction. This works exceptionally well when the existing eyeglasses contain a strong spherical or cylindrical component. The most practical use of a trial frame or clip-ons is to allow the patient to experience the change in correction before investing in a new pair of glasses.

## Determination of the Cylinder Axis

The "clock dial," a standard target in most ophthalmic projector systems, is a circular chart with radii drawn at 30° intervals. When the correct power

toric lens is interposed along the appropriate axis, each image is circular and all of the radii appear equally dark (Fig. 2.3.6). The starting point of the test is to have sufficient plus lens power in the tentative correction so that the focal points of both principal meridians are anterior to the retina yet are recognizable. This "fogging" technique serves to inhibit the natural accommodative response to blur; any focusing effort only further blurs the image. In practice, the initial starting sphere (obtained by omitting the minus cylinder from the net retinoscopy result, the previous spectacle correction, or the autorefraction result) is placed before the eye under test. For an eye correctable to 20/20 (6/6), sufficient plus lens power is added to blur the 20/40 (6/12) line of letters, usually at least 1.00 D.

In eyes with more astigmatism, enough plus power must be added to fog the least myopic or the most hyperopic meridian. The clock chart is projected and the patient is asked, "Which, if any, spokes on the wheel are darker?" Because the details of the chart are standardized at the 20/30 level, incremental reductions in plus power are required until some of the lines are clear. If no astigmatism is present, all of the spokes remain equally blurred as plus power is reduced. In astigmatic eyes, the focal line produced by the flatter principal meridian is closer to the retina and appears darker or bolder. With high values of astigmatism, one or two lines are prominent, whereas at lower values several lines may initially appear equally dark. The center of the group is identified by the patient. A direct method of communicating the correct axis is to have the patient point out the darkest meridian with a laser pointer.<sup>15</sup> The axis of the correcting minus cylinder is placed at 90° to this line.

Another simple method is to use the lowest "clock time" of the darkest line and multiply by 30. For example, if the vertical line were darkest, the patient would respond, "The 6 o'clock/12 o'clock line." The correcting cylinder should be placed at axis 180° (6×30). Minus cylinder lenses are then added in 0.25 D increments until all the spokes are equally dark. To maintain the refractive fog, a +0.25 D sphere is added for each -0.50 D of cylinder that is added. When equality of the spokes is reported, the process should be continued until reversal occurs to ensure that the full cylinder power has actually been identified.

Because the meridians on the clock chart are 30° apart, the true axis may lie between them. There are several other commonly used charts that can refine the axis more precisely. The sunburst chart has radial lines that are only 15° apart, but it is often difficult to communicate the precise axis to the examiner because of fluctuations in response related to minor head movements. The Paraboline rotary slide (Fig. 2.3.7) has two symmetrical parabolic arcs whose asymptotic ends approximate the image of an arrowhead.<sup>16</sup> With the eye in a "fogged" state, the slide is rotated until both halves of the arrowhead appear equally dark. The axis can be read from a protractor projected onto the screen. Along the principal axes of the pattern is a cross of dotted lines, which is then used as described before to determine the correct cylinder power.

The Jackson cross-cylinder (JCC) test is perhaps the most commonly used method for subjectively determining the presence of astigmatism and for refining the power and axis of a refractive cylinder. It relies on the

**Fig. 2.3.7 The Paraboline Rotary Projection Chart.** The axis of the correcting lens is determined by rotating the slide until both arms of the pattern appear equally dark.

**Fig. 2.3.9** The refractor-mounted Jackson cross-cylinder is in place to check for axis orientation of a cylinder of axis 90°.

**Fig. 2.3.8 The Handheld Jackson Cross-Cylinder.** Note the red circles at the ends of the minus axis. (Courtesy Scott Brodie.)

principle of placing the circle of least confusion on the retina. A crossed cylinder is a lens whose principal powers are equal and opposite in sign. Each end of the minus axis is marked with a red dot, whereas the plus axis has white dots. The rotating handle in the manual lens and the pivot axis in the refractor-mounted JCC is 45° away from the principal meridians to allow the lens to be flipped quickly into two primary positions. When the circle of least confusion lies on the retina, meridians are equally out of focus (see Figs. 2.3.8, 2.3.9).

A cylindrical lens whose minus axis is lined up exactly along the astigmatic plus axis of the eye produces a resultant spherocylinder whose axis is also coincident. However, if the correcting lens axis is not aligned with the astigmatic axis of the eye, the resultant cylinder's axis lies oblique to the other two axes. The power of the resultant cylinder varies in proportion to the amount of axial rotation between the axis of the eye and the axis of the lens. The JCC is used to determine the correct axis and power of the correcting lens by producing larger or smaller circles of least confusion on the retina in each of its flipped positions. The correcting cylinder can be changed until the sizes of the blur circles are equal. As in all astigmatic correction techniques, the cylinder axis needs to be established before the power can be determined.

When the JCC is used to locate the correcting axis, the images are equally blurred when the principal meridians of the JCC are equally misaligned with the true correcting axis of the eye. To refine the astigmatic correction, the starting point correction is placed before the eye. The handle of the

JCC is aligned along the minus axis of the spectacle lens, placing the JCC's principal meridians each 45° away. Using a target one line larger than the best acuity obtained through the tentative correction, the examiner flips the JCC and asks the patient the famous question, "Which is better—one or two?" The endpoint is the answer, "They are equally blurred." If one position of the JCC produces a better image, the axes of both the tentative correcting lens and the JCC are moved 5° in the direction of the red dots on the JCC (if using minus-cylinder trial lenses—if using plus-cylinder trial lenses, rotate the tentative correcting lens toward the preferred orientation of the white dots). In most refractor models, the cylinder axis and the JCC rotate together. The lens is flipped again and the patient is given the opportunity to compare the image through each lens. At the axis at which equality of blur is located, the lenses should be rotated another 5° in the same direction. If the previous response was accurate, the new position should produce a reversal in direction.

## Determination of Cylinder Power

To determine the correct minus cylinder power, the JCC is rotated until one set of principal meridians overlies the minus axis of the correcting lens. The handle of the manual JCC is now 45° away. On the refractor units, the position is marked by a click-stop detent. Using the same line of letters, the JCC is flipped and again the patient is asked to choose the better of the two images. If the JCC's minus axis, marked by the red dots, is aligned with the cylinder axis, a cylinder of 0.25 D more minus power is added to the correction. If the better image is produced when the plus axis, marked by the white dots, is aligned, the cylinder power is adjusted by adding +0.25 D. To ensure that the circle of confusion remains on the retina, for each 0.50 D of cylinder that is added, a 0.25 D sphere of the opposite power should be added. The procedure is repeated until the two images are equally blurred. Going one lens past to reversal ensures that the correct lens is selected.

## Rechecking the Sphere

Once the proper cylindrical correction has been established, the final sphere needs to be determined. One simple technique is to "refog" the eye using plus lenses to minimize the effects of uncontrolled accommodation. Obviously, this is more of an issue in younger individuals who have a large accommodative reserve. Using the line of expected best acuity, the power is reduced by 0.25 D at a time with a sufficient intervening pause to allow the patient to attempt to interpret the letters. Once the letters are identified, the next smaller line is presented. If these letters are not clearly recognized, power is reduced by another 0.25 D. If the letters are still not clear, the previous lens probably produces the sharpest unaccommodated focus. If the letters are seen, the process is repeated with the next smaller line. Many individuals have the capability to see details smaller than those on the 20/20 line. It is important to record the best acuity to establish a baseline for future comparisons.

**Fig. 2.3.10** When letters on the green side of the chart are clearer, more spherical plus power needs to be added.

Another technique commonly used to refine the final sphere is the duochrome test, which makes use of the chromatic aberration of the eye.<sup>17</sup> White light entering the eye is refracted according to its component wavelengths. In an emmetropic eye, blue light focuses about 1 D myopic, whereas red light focuses about 0.5 D hyperopic but equidistant from the retina. The duochrome test uses a pair of colored filters built into the projector chart, the peak transmission of one at 530 nm (green) and of the other at 670 nm (red) (Fig. 2.3.10). In corrected emmetropia, a matched presentation of letters is equally blurred on each side of the chart. With the best spherocylindrical correction, the patient is asked to look at the letters on the green side. They remain in focus only when accommodation is relaxed. Because the letters on the red side can be made clearer by accommodating for them, the patient is asked to look quickly at the letters on the red side and then back at the green and compare their clarity. If the letters on the green side are clearer, the correcting sphere is changed by 0.25 D in the plus direction. If the letters on the red side are clearer, 0.25 D is added in the minus direction. This test is sensitive enough for 0.25 D to cause a reversal in clarity.

## Final Checks

### Accommodation

Cycloplegic eyedrops can be used to eliminate accommodation during the examination. In most cases, the results of a cycloplegic refraction are not prescribed as a correction. Rather, this type of examination is used in selected circumstances to determine the baseline refractive status of the eye. There are two common situations in which this is valuable:

- In young individuals who are suspected of accommodative spasm, especially when it is accompanied by esophoria or esotropia, it is important to prescribe the strongest plus power correction in order to relax accommodation. A follow-up examination not under cycloplegia is usually required to determine the maximum amount of lens power that can be tolerated in the natural state.
- Protocols for refractive surgery usually dictate that the cycloplegic refractive power of the eyes be determined before the procedure.<sup>18</sup>

### Binocular Balance

The entire procedure is repeated for each eye to produce two monocular subjective prescriptions. Assuming that the patient has clear, single binocular vision, the effects of compensating for an existing heterophoria or the effects of summation of vision from both eyes may alter the lens powers chosen for the binocular subjective prescription.<sup>19</sup> The process is usually accomplished in two steps.

The first is to ensure that equal accommodative effort is present between the two eyes. If the best-corrected vision is approximately the same in each eye, vision is fogged with +0.75 D lenses. Sufficient vertical prism is placed in front of each eye to produce two separate images of the isolated 20/40 (6/12) line. The patient is asked to compare the clarities of the upper line and the lower line. If they appear equally blurred, +0.25 D is added to one eye and they are compared again. The other eye should now see slightly

more clearly. The lens is removed and the process repeated for the other eye. Adjustments are made until the images are as equally blurred as possible. If there is no pair of lenses that produces an equality of blur between the two eyes, the pair that gives the slightly better image in front of the dominant eye is often preferred.

The best acuity line is then isolated on the chart. The fogging lenses are reduced from both eyes by 0.25 D at a time, allowing sufficient time between stages for the patient to adjust to the lens change. In the same way as with the monocular subjective test, the lens power that gives best acuity without inducing accommodation is usually the final choice. The duochrome test offers an alternative method of determining the lens powers that produce a sharp unaccommodated retinal image.

The same technique can be employed with eyes that have a moderate discrepancy in best-corrected vision, either from amblyopia or from some other abnormality. The lens powers can be balanced using a larger line of letters, for example the 20/80 (6/24) line, and then reduced to the best binocular acuity, which is that of the better eye. This solves the dilemma of trying to determine the best monocular subjective correction in an eye with poor visual discrimination.

Binocular refraction is an infrequently used technique in which both eyes are fixating while the monocular refraction is measured. Most contemporary devices use some form of vectographic separation in which a polarized target is presented to each eye through interposing polarized analyzers with a different axis in front of each eye. This has the advantage of mimicking the normal form of seeing, incorporating all of the patient's binocular efforts including horizontal and vertical phorias. In addition, this method offers the only way to identify a cyclophoria in which the astigmatic axes of the eyes are different under binocular conditions from when observed monocularly.<sup>20</sup>

Trial frame confirmation of the final prescription is often overlooked but is an extremely valuable verification of the comfort and acuity of the new lens power. Although an examination room of length 20 ft (6 m) is considered to be the equivalent of optical infinity, 0.17 D of accommodation is still required at that distance. It is psychologically reassuring for the patient to step out of the examination room and view the end of the hallway or, better still, the other side of the street, through the new lenses. This small investment of time may save lengthy follow-up visits that could result from miscommunication in the examination room.

If the cylinder correction is similar to that of the patient's old glasses, it is relatively straightforward to have the patient hand-hold spherical trial lenses in front of the glasses and compare vision with and without the change in prescription. This is a simple way to determine which is the more satisfactory lens correction when a discrepancy exists between the monocular subjective and the binocular subjective tests. As the monocular subjective test's endpoint is best acuity and the binocular subjective test's endpoint is equality of accommodation, some patients may have a slight difference in right and left eye acuities through the binocular prescription. This refinement offers them the opportunity to observe the difference between the two corrections and to make a practical choice between them.

If there is some doubt about the visual comfort of the change, the lenses can be held in position with a clip-on lens holder while the patient takes the opportunity to walk around and adjust to the difference. In some cases, it may be beneficial to allow patients to borrow the lenses and holders overnight to evaluate the lens changes in their own environment. It is important to mark the right and left lenses and, if cylinders are required, to provide a sketch to help align the axis marks.

A similar procedure can be used when the change in correction is a spherocylinder. It is unwieldy to place and remove more than one lens in front of the patient's glasses. If the new cylinder axis is different from that of the old eyeglasses, a calculation of resultant cylinder axis and power is required to determine the appropriate lens to hold in front of the glasses. In such a situation, it is more practical to place the new correction in a trial frame and to let the patient alternately view at a distance through the trial frame and the old glasses. The trial frame interpupillary distance, the vertical lens position, and the pantoscopic angle should be adjusted correctly, especially with strong lens powers.

## REFRACTING AT NEAR

The near correction is the distance correction with sufficient plus additional power (the "add") to satisfy individual needs for clear, comfortable single vision at a desired near point. Although there are normative tables for determining an add according to the patient's age, these simply function as benchmarks to help the examiner recognize a potential overcorrected or undercorrected condition. This is an important time to listen to

your patient. Although patients are notoriously inaccurate when estimating their working distances, the description of how they use their eyes at near helps to determine not only the strength of the lens power required for tasks at near, but also the form in which the correction will be most effective. For example, a presbyope who requires a +2.00 D add for reading may be very satisfied with a bifocal correction for most activities but may require a +1.25 D add in single vision lenses to work at a computer terminal.

One rule of thumb that has gained wide acceptance is that the near add at a given distance should allow half of the patient's accommodative amplitude to remain in reserve. The amplitude is determined by measuring the closest point at which an individual can maintain focus through the distance correction. For a prepresbyope, this simply means measuring the distance at which a fine line of print can no longer be focused. This distance, measured in centimeters, is divided into 100 to convert it into amplitude of accommodation. A presbyope needs to place a plus lens over the distance correction to be able to see the fine print. The closest distance to which the print can be moved before blurring is again converted into diopters and the power of the interposed lens subtracted to give the amplitude (Box 2.3.1, Fig. 2.3.11).

A clinical method commonly used to measure the near add is the fused cross-cylinder test. A cross made up of multiple horizontal and vertical lines is presented to the patient at a distance of 40 cm. A JCC with its minus axis vertical is placed in front of the distance correction. The patient is asked to compare the boldness of the horizontal and vertical lines of the cross. If no add is required, the lines are equally dark. If the horizontal lines are darker, plus power is added binocularly in 0.25 D increments until the lines are equally black or until the vertical lines become more prominent. This lens power becomes the tentative add.<sup>21</sup>

The final add is determined by verifying that the add is appropriate for the patient's visual needs. The range of clear near vision is the linear distance between the far point of the near lens (usually the reciprocal of the add power) and the near point of accommodation through the add. Because the range of vision is inversely proportional to the power of the lens, many experienced refractionists prescribe the weakest add that meets the patient's demands.<sup>22</sup> For most individuals, having a larger range in which objects are clear overrides the desire to see extremely fine print at a close distance. It is often helpful to patients who are receiving their first

presbyopic correction to have lenses held in place to demonstrate that their near correction will, of necessity, blur their distance vision.

In situations where an anisometropic distance correction is required, it is wise to measure the ranges monocularly to account for any optical effects related to the unequal strength of the lenses.<sup>23</sup> Unequal adds may be prescribed in certain other situations to keep the near and far points of the ranges at similar distances. As with any significant change, a trial frame evaluation of the new correction may help to identify any potential difficulties before glasses are fabricated. In some cases of anisometropia, bifocals may produce reading discomfort because of an induced vertical prismatic effect in the reading position of gaze. Specially designed slab-off lenses or single-vision reading glasses may be required.

Patients who require higher bifocal adds may not have sufficient accommodation to overlap their distance and near ranges of vision. This "dead zone" is problematic in certain jobs and avocations. An accountant may not be able to see a calculator clearly in its normal desktop position, and a violinist may have difficulty reading from a music stand. Although trifocals or progressive lenses may be satisfactory, special use lenses may be required, such as low-add bifocals with a high segment line.

Computer users who must also read place a unique set of demands on their glasses. The video screen is usually just below eye level at arm's length or slightly closer, whereas reading material and the keyboard are positioned lower and somewhat closer. It is often worthwhile to have patients adjust one of the computer terminals in the examiner's office to simulate their workstation conditions.<sup>24</sup> Eye-to-screen and eye-to-keyboard measurements can be used to determine the necessary add powers. Many presbyopic computer operators have occupational bifocals in which the top section of the lenses has the intermediate correction and the lower portion is set for the keyboard distance. When the operator leaves the workstation, these glasses are left at the terminal and a conventional correction is used. Progressive lenses often work very well at the computer, though the patient should be warned that the greater magnification at the bottom of the lenses will make the computer screen appear trapezoidal in shape.

The vast majority of presbyopic refractive errors are now corrected using multifocal progressive lenses. The continuity of focus that can be achieved by slight shifts in vertical head position combined with the lack of a visible line in the lens identifying the wearer as "older" has made this the default presbyopic lens design in affluent countries. In recent years, special use lenses have proliferated offering even more comfort and functionality for those who spend considerable time in activities with a high visual demand at near or intermediate distances.

### BOX 2.3.1 Calculated Near "Add" at Any Distance Should Keep Half of the Patient's Accommodative Amplitude in Reserve

With an extra +1.50 D lens the near point of accommodation is 40 cm (2.50 D).

The patient's amplitude is 1.00 D (2.50 D – 1.50 D).

For a working distance of 50 cm, 2.00 D of accommodation is required.

Therefore the patient's "add" for that distance is +1.50 D [2.00 D – ½ (1.00) D].

**Fig. 2.3.11** A near card is placed in front of the phoropter and slid back and forth to determine the closest distance at which the print can be seen before blurring takes place.

### ADDITIONAL SUBJECTIVE TECHNIQUES

Bedside examinations, nursing home visits, and equipment failure are examples of situations that require skill in trial frame refraction. When poorly controlled ambient lighting exists, retinoscopy is often an estimate at best. A retinoscopy rack made up of a battery of spherical lenses (Fig. 2.3.12) arranged in ascending order of power can be used to determine the

**Fig. 2.3.12** Plus and minus racks of spherical lenses, normally used for retinoscopy screening, are also useful to determine an approximate subjective spherical equivalent lens.

subjective spherical equivalent. Using this power as the initial trial frame starting lens, a handheld JCC can be used to determine the presence of any astigmatism. The handle is positioned along a true oblique meridian ( $45^\circ$  or  $135^\circ$ ) so that the principal powers are along the horizontal and vertical meridians. The lens is flipped and the patient is asked whether either position is better. If not, the handle is repositioned horizontally so that the principal powers now lie along the  $45^\circ$  and  $135^\circ$  meridians and the procedure is repeated. If again there is no preference, there is no clinically significant astigmatism in that eye. If the patient indicates a preference in any of those positions, the JCC tests proceed as described earlier.

Some examiners locate the axis of a tentative cylinder by rotating the lens and asking the patient to indicate the position where vision is the clearest. For strong cylinders, this is an accurate and repeatable technique. However, for low-power cylinders a range of axis positions exists that produce clear vision for most observers.<sup>25</sup> A modification of this test to increase its accuracy is to rotate the lens until a small line of letters first blurs noticeably then rotate the lens back in the opposite direction to first blur. The midposition is the correcting axis. This test is highly dependent on an acutely observant patient.

One drawback of the JCC is its reliance on the patient's visual memory to determine preferences. Modifications of the refractor-mounted versions exist that use split prisms to produce a simultaneous presentation of both positions of the JCC. The lens and device can be rotated together until the images are equally blurred to locate the cylinder axis. In the same way, the power can be determined by changing the correcting cylinder power until both images appear equal.

In situations where vision in an eye is very poor and no other instruments are available, the stenopeic slit can be used to screen for a high degree of astigmatism. It functions as a series of pinholes along a meridian. A trial frame or clip-on device is used to place the trial lens stenopeic slit in the lens cell and rotate it slowly. If there is a position that produces improved vision, it is treated as a principal meridian of the eye. With the slit still in place, spherical plus and minus lenses are positioned in front of it. A convenient method is to use the retinoscopy rack. When the lens power that gives the most improvement has been established, the stenopeic slit is rotated  $90^\circ$  and the procedure repeated. The two spherical lens powers are considered to be the correcting lens powers for each of the principal meridians. The powers are combined in a spherocylinder lens that is placed in the trial lens cell. If vision is improved sufficiently, it may be possible to refine the correction using conventional methods (Fig. 2.3.13).

## RETINOSCOPY

### Retinoscope

Every time a close-up photograph is taken of the face of a subject and a vivid red pupil (called *red eye*) seen instead of the usual black pupil, the

**Fig. 2.3.13** A Stenopeic Slit Is in Place to Check Along the 135th Meridian. Once the spherical power has been determined, the lens should be rotated  $90^\circ$  and the spherical power measured along the 45th meridian. The two powers can be combined into a spherocylindrical lens.

essence of retinoscopy is captured. The red reflex is produced when the flash lamp is positioned close to the optical axis of the camera.

The source of the red reflex is the aerial image of the blood-filled choroid superimposed on the pupil. Because the image is very small, it is seen only if the optical systems of the subject's eye and the camera, respectively, are close to alignment. Because the aerial image cannot be in the plane of the pupil, it must always be out of focus when the plane of the face or eye is in sharp focus. Von Helmholtz realized that the origin of the reflex must be the fundus itself and developed the ophthalmoscope to focus on the details of the fundus.<sup>26,27</sup> Thus the position of the aerial image of the fundus is determined by the optical components of the eye. Therefore determination of the position of the image can lead to determination of the refractive error of the eye. Cuignet, a French army ophthalmologist who measured the refractions of a large number of army recruits, must be credited with the development of a better way to define the position of the aerial image.<sup>28</sup> His method always brought the aerial image to the same location in space, at the examiner's eye, a principle employed by most contemporary retinoscopists. Subtraction of the dioptric-value equivalent of the "working distance" determined the power of the lens required to correct the refractive error.

### Optics of Retinoscopy

The essence of retinoscopy is to illuminate the retina and then locate the image of the retina in space. Thus the retinoscope combines a light source with an observation aperture (i.e., peephole). The position of the retinal image is called the *far point*. Its position in dioptric units is equal to the refractive error. Thus the eye may be considered as an element in an optical bench. When the light rays that leave the eye are made visible, the far point can be located and the refractive error calculated. Unfortunately, a side-view analysis of the human eye as though it is on an optical bench cannot be done. However, with this side-view analysis in mind, the mechanism of retinoscopy can be understood.

For the purposes of this description, it is assumed that a side-view analysis is possible. The retinoscopist places lenses in front of the patient's eye so that the patient's far point is focused at the peephole of the retinoscope. For example, the emmetrope's far point is at infinity. If the retinoscopist works at a distance of 25 inches (66 cm) from the patient (called the working distance), a  $+1.50$  D lens brings parallel light to a focus at 25 inches (66 cm) from the patient's eye. The far point of the myope lies between the examiner and the patient (Fig. 2.3.14). A minus lens of the appropriate power brings the image to the peephole of the retinoscope. The refractive error equals the dioptric power of the minus lens needed less that of the working-distance lens ( $+1.50$  D). Thus, if a  $-5.00$  D lens is needed to bring the far point to the examiner, then the refractive error is  $-5.00$  D  $+ 1.50$  D  $= -3.50$  D. The far point of the hyperope is theoretically behind the head of the patient. A plus lens of the appropriate power brings the far point to the peephole of the examiner. Thus, if a  $+5.00$  D lens is needed to bring the far point to the examiner, then the refractive error is  $5.00 + 1.50$  D  $= +6.50$  D.

### Neutrality

Cuignet found the position of the far point by using a version of the Foucault knife-edge test. Imagine a thin, sharp knife that moves across the beam of light that leaves the patient's eye. If the knife edge passes across the point of focus, then the knife edge blocks all the light for an instant, after which all the light reappears; the edge of the peephole of the retinoscope may

**Fig. 2.3.14** The Far Point of the Myopic Eye Lies Between the Patient and the Retinoscopist.

be considered such a knife edge. If the far point is brought to a focus at the peephole, then the focused light appears to vanish and reappear with a slight side-to-side motion of the peephole. This situation is called neutrality and represents the endpoint of retinoscopy. It is at this endpoint that the power of the lens in front of the patient's eye minus the +1.50 D working lens yields the value of the refractive error.

### With and Against Motion

The image that emerges from the patient's eye before neutrality is reached is significant. In a myopic eye, as the examiner moves the illumination light upward, the retina is illuminated in an upward direction. The real, inverted image of the retina is focused between the patient and examiner, and the retinal image appears to move downward in a direction opposite to the movement of the retinoscope. This is called *against* motion. Minus lenses are placed in front of the patient's eye until the focus is brought to the plane of the peephole, at which point neutrality is seen. In a hyperopic eye, as the beam from the retinoscope moves upward, the retina is illuminated in an upward direction. The virtual, upright image of the retina appears illuminated in an upward direction. Because the image moves in the same direction as the retinoscope, the motion is called a *with* motion. Plus lenses are placed in front of the patient's eye, the image is moved to the plane of the retinoscopic pinhole, and neutrality is seen.

### Other Clues

The retinoscopist must be aware of other subtle clues that differentiate fine with and against motions from neutrality. For example, the aerial image becomes larger the closer it is to the examiner's eye. A closer aerial image also appears to move faster because more of the closer image fills the peephole than does a smaller, more distant aerial image. A small movement of the peephole crosses a larger percentage of the aerial image and gives the appearance of a faster movement. The closer to neutrality, the faster is the movement of the reflex. In a similar vein, the brighter the reflex, the closer it is to neutrality. Here again, the closer the aerial image is to the retinoscopist (Newton's law), the brighter it is.

### Myopia Estimation

If the initial retinoscopic movement is slow and dull, with movement, then high myopia is present. To estimate quickly the amount of myopia without using trial lenses, simply move toward the patient and simultaneously move the retinoscope slowly from side to side. As the far point is reached, the endpoint of neutrality is given. The distance from the patient is the far point and must be converted into diopters. Thus, if neutrality takes place

at 75 inches (20 cm), the amount of myopia is 5.00 D (no working distance compensation is needed).

### Astigmatism

To determine the presence of astigmatism, simply sharpen the streak and slowly rotate it to 360°. If little or no astigmatism exists, the retinoscopic streak reflex always is parallel to the intercept. A break phenomenon occurs when the reflex is not in perfect alignment with the intercept as the streak is rotated. The orientation of the streak reflex when it lies parallel to the intercept indicates the direction of one of the major meridians of the astigmatism. The examiner must find the lens of neutrality for a side-to-side movement along that meridian and establish neutrality for the meridian 90° away. For example, assume that the maximum break phenomenon is along the 90° meridian. Rotate the streak into a horizontal position and move the retinoscope up and down (along the 90° meridian). Imagine that a +4.50 D sphere neutralizes the vertical movement. Now rotate the streak vertically and move it side to side along the 180° meridian. With the +4.50 D sphere in place, a -2.00 D cylinder of axis 90° neutralizes the side-to-side movement. Subtraction of the +1.50 D power of the working distance lens from the dioptric power of the sphere yields a +2.00 D sphere with a -2.00 D cylinder of axis 90°.

# Correction of Refractive Errors

Bing Chiu, Joshua A. Young

## 2.4

**Definition:** Refractive errors may be corrected by means of spectacles, contact lenses, orthokeratology, intraocular lens implants, and keratorefractive surgery.

### Key Features

- Spectacle lens advantages: inexpensive; suitable to correct myopia, hyperopia, astigmatic refractive errors, and presbyopia; no permanent ocular alterations. Drawbacks: some patients may reject for cosmetic reasons; may cause image jump, object displacement, and alter retinal image size.
- Contact lens advantages: excellent cosmetic appearance, free from prismatic effects, minimize astigmatic distortions and problems with alterations in retinal image size. Drawbacks: correction of astigmatic errors and presbyopia may be difficult; expose patients to risk of corneal oxygen deprivation and corneal infections.
- Orthokeratology advantages: patients may be able to function without glasses or contact lenses during daytime. Drawbacks: require nighttime contact lens wear; correction may wane during daytime hours.
- Intraocular lens implant advantages: preferred correction for aphakia; may allow for correction of extreme myopia in phakic patients. Drawbacks: limited correction of presbyopia, astigmatism; phakic intraocular lenses may induce cataract formation.
- Keratorefractive surgery advantages: may eliminate need for glasses. Drawbacks: less predictable for correction of larger refractive errors; may destabilize cornea; risk of complications (small).

### INTRODUCTION

In an ideal eye, the combined optical contribution of the front of the eye focuses incoming rays of light onto the retina to produce a clear image. If this optically ideal eye requires no aid or accommodation to focus distant objects onto the retina, the eye is said to be emmetropic. Conversely, if an eye in its relaxed, nonaccommodating state and devoid of other pathology fails to produce a clear image on the retina from rays of light of a distant object, the eye is said to be ametropic. Ametropia encompasses a wide range of optical imperfections including myopia (nearsightedness or shortsightedness), hyperopia (farsightedness or long-sightedness), and astigmatism, itself a collection of different optical imperfections. Indeed, an almost limitless number of optical abnormalities exist beyond these, but such optical aberrations are not amenable to correction by spectacles, and discussion of these will be limited in this chapter.

In addition to the very obvious disadvantage of reducing visual clarity, ametropia may be an indicator of more serious ophthalmic disease. An adult whose previously stable refraction has begun to demonstrate increasing myopia may be demonstrating the refractive effect of a maturing nuclear cataract. A 20-year-old whose astigmatism has begun to worsen may be suffering from progressive keratoconus, a disease of ectasia of the most refractively important part of the eye, the cornea. The highly hyperopic middle-aged woman is at substantial risk of angle-closure glaucoma for precisely the same reason for which she is hyperopic, a small and therefore crowded eye.

A number of clinical modalities exist to correct ametropia. Each of these has limitations, and different types of correction are advantageous for different clinical settings. The simplest of these and the only method without medical risk is spectacle correction.

### SPECTACLE CORRECTION

Evidence of spectacle use dates to at least the late thirteenth century. Although this certainly implies that people with refractive errors could seek no remedy for the countless millennia that preceded the invention of spectacles, it has been suggested that ametropia, particularly myopia, was far less common in the ancient world than it is at present.

### Spectacle Material

Whether a person wears glasses for correction of refractive error, protection of eyes, or for cosmetic reasons, the materials of the lenses can play a significant role. For the patient who desires the best optical quality throughout her or his visual field, a thin lens with significant peripheral blurring might be a poor choice. Likewise, for the patient for whom impact protection is paramount, a glass lens that can easily break and shatter would be unsuitable.

Spectacle lenses are manufactured from a variety of materials<sup>1</sup> with characteristics that can be condensed into a few properties that describe the optical quality, strength, and density. The ideal material would be thin, lightweight, impact and scratch resistant, inexpensive, and devoid of optical distortion. The variety of available materials may be seen as a demonstration that no single optimal material exists. One unwanted property of lens material is the tendency to disperse white light into its component wavelengths. Rainbows are pretty in the sky but the color fringing that results from wavelength dispersion in spectacles is distracting and degrades image quality. This wavelength dispersion is referred to as chromatic aberration, and the degree to which materials disperse wavelengths is quantified as the Abbe number or V-number. Materials that minimize chromatic dispersion—those with higher Abbe numbers—are generally more desirable.

Of course, the primary reason for which lenses are designed is to bend or refract light. The degree to which a spectacle lens bends light is a function of its curvature and of the material from which it is made. For any given shape, certain materials will bend light more than others. The degree to which a material can bend or refract light is a function of the speed of light through that material. We generally think of the speed of light as the immutable value  $c$  or 299,792,458 m/s, but of course this is the speed of light through a vacuum. Through any other medium, light propagates at a velocity lower than  $c$ . Media through which light moves especially slowly have the greatest ability to refract. The degree to which a material is capable of refracting light is given by the ratio of  $c$  over the speed of light through the material. This ratio is called the index of refraction, and higher values indicate a greater ability of a material to refract light. Because a lens with greater intrinsic ability to refract light requires a less curved surface to achieve the desired refraction, high refractive index lenses can be made thinner than low refractive index lenses. For this reason, patients with high degrees of ametropia often opt for high index lenses.

Spectacles also serve as a barrier between the environment and the eyes. For some patients—those who are monocular or amblyopic and those who are engaged in work in which ocular trauma is possible—the strength of the lens material may be its most important property.<sup>2</sup> Standards are set by the US Food and Drug Administration (FDA) and American National Standards Institute (ANSI) for resistance of a material to penetration or shattering. Although glass lenses offer excellent optical quality and scratch resistance at a low cost, glass has fallen out of favor because of its poor impact resistance and high specific gravity, making it a heavy material. Plastic, also known as hard resin or Columbia resin (CR-39), has become the most common material for spectacles. It is light, impact resistant, and versatile, naturally UV blocking, and can be easily tinted or treated to be scratch resistant. However, plastic has a low index of refraction and

a thicker lens is therefore required. A stronger material, polycarbonate, is commonly used in protective wear. Originally made for aerospace and used in helmet visors and space shuttle windshields, this petroleum derivative plastic polymer has a high refractive index and low specific gravity with very high impact resistance. Although these lenses are thin and lightweight, polycarbonate has a relatively low Abbe number, and so high chromatic dispersion results. Polycarbonate is also prone to scratches, making scratch-resistant coating essential.

For high refractive errors, high refractive index materials can be beneficial, although not without costs—both optical and financial. Plastic or glass materials that are made with higher index of refraction (i.e., over 1.6) are lighter and thinner but are also prone to more chromatic aberration and distortion at the periphery of the lens. They also tend to be less impact and scratch resistant.

## Monofocal Spectacles

Monofocal spectacles correct for spherical refractive errors such as myopia and hyperopia, astigmatic refractive errors, and for combinations of spherical and astigmatic errors. For patients incapable of any degree of accommodation, for example patients who have undergone cataract extraction, these spectacles bring clear focus to objects at only a defined distance from the eye. For example, monofocal distance spectacles would not bring near objects into clear focus for such a patient. In clinical practice, monofocal lenses are prescribed to young, nonpresbyopic patients for all tasks and for presbyopic patients for limited tasks. For emmetropic presbyopic patients, those with naturally good distance vision but for whom accommodation is inadequate, monofocal reading glasses often are prescribed.

Clinicians prescribing monofocal spectacles specify only three parameters for each eye: the power of the spherical correction, the power of the astigmatic correction, and the orientation (axis) of the astigmatic correction. Although this prescription may compensate for the patient's refractive error, a number of factors other than these determine whether the patient will tolerate the prescribed lenses. These factors have in common the drawback that image distortion is intrinsic to spectacle correction. Most important, distortions arise from asymmetrical image magnification and may be illustrated in this thought experiment: Imagine an emmetropic patient looking through a telescope at a distant object. The telescope, a Galilean telescope in this case, consists of a plus-power or converging objective (the lens at the large end of the telescope) and a minus-power or diverging eyepiece. For this experiment, let's imagine that the minus-power eyepiece is a contact lens. Indeed, the telescope would exhibit the same degree of magnification if the eyepiece were a conventional lens or a contact lens. If we further imagine that our patient, rather than being emmetropic, has instead a refractive error equivalent to the contact-lens eyepiece, she or he would experience the same degree of magnification as our original emmetrope. Our ametropic patient is hyperopic. We know this because the correcting lens (i.e., the objective of the telescope) is plus powered and thus we see that hyperopes corrected with plus spectacles experience a degree of image magnification. The case of the myope is identical in every regard except that the "telescope" is now oriented backward and produces object minification.

The magnification produced by spectacles is generally tolerated well by patients as long as its magnitude is similar in each eye. However, asymmetrical magnification of only a few percent can produce symptoms sufficient to make spectacle correction intolerable. The degree of magnification is a function of two variables: the dioptric power of the spectacle lens (equivalent to the telescope's object lens) and the distance between the spectacle lens and the eye, known as the vertex distance (and equivalent to the length of the telescope's tube).

The condition of perceived difference in image size between right and left eyes is called aniseikonia. As a general rule, adults who are unaccustomed to large differences in prescriptions between right and left eyes will tolerate no more than 3 or 4 diopters of asymmetry in spectacles. This challenge arises clinically in the case of patients who are developing an asymmetrical increase in myopia from a maturing nuclear cataract (so-called myopic shift) or after cataract surgery if the refractive errors are substantially asymmetrical postoperatively.

Symptoms attributable to asymmetrical magnification are not limited to aniseikonia from asymmetrical spectacles. Asymmetrical magnification also can produce symptoms monocularly. Because the degree of magnification produced by a spectacle lens is dependent partly on the distance between the lens and the eye, the degree of magnification or minification is least at the center of the spectacle lens where the lens is closest to the cornea and increases farther away from the center of the

spectacle lens. This produces a type of distortion characteristic to each type of lens.

Spectacles to correct myopia employ minus-powered lenses. These lenses produce minification and, because the periphery of the image is minified to a greater extent, produce a sort of distortion in which the periphery of the image is rendered at a smaller scale than the center. This is referred to as "barrel distortion." Such distortion is readily observed when looking into a convenience store mirror, when looking at one's self in a mirrored sphere like a ball bearing, or viewing a scene through a fisheye lens.

Similarly, plus-powered spectacles for the correction of hyperopia produce distorted images in which the periphery is more magnified than the center. This "pin-cushion distortion" also may be observed when using a magnifying glass<sup>3</sup> (Fig. 2.4.1).

Perhaps the most disturbing sort of asymmetrical magnification induced by spectacle lenses is the meridional magnification intrinsic to astigmatic lenses. In this case the meridian of highest plus power produces relative magnification compared with the meridian of highest minus power. The net result is to produce images that are short and fat, tall and skinny, or magnified obliquely. This is especially disturbing when, as is often the case, astigmatic axes are oblique and at mirror-image orientations in the two eyes. Oppositely oriented meridional magnification may be misinterpreted as distortion in depth perception and can make spectacles intolerable even if the right and left lenses are of equal dioptric power.

## Bifocals

Traditional bifocal and trifocal lenses have been largely displaced by progressive lenses. Still, these older forms remain in wide use and in some clinical settings have advantages over the newer progressive designs. Bifocal lenses are distinguished by discrete segments for distance and for near with an abrupt transition between the two<sup>4</sup> (Fig. 2.4.2). Unlike monofocal

Fig. 2.4.1 Types of Distortion Induced by Spectacle Lenses. (Courtesy Joshua Young and Wikipedia, "Barrel distortion"; public domain.)

Fig. 2.4.2 Bifocal Segment Types and Their Optical Centers. (Courtesy Joshua Young.)

lenses, the prescriptions for which are ground into the back surface of the lens, bifocal segments are applied to the front surface. Bifocal designs take a number of forms, and the appropriate choice of bifocal segment is a function of the lens to which it is applied.

All bifocal segments are plus-dioptic powers. As such, they may be thought of as portions of a larger plus-powered lens. The round-type bifocal would then derive from the top of a plus-powered lens and the flat-top from the bottom of a plus-powered lens. This is highly significant because each type of bifocal adds a certain degree of prism to the bottom of the spectacles and produces a certain amount of discontinuity at the line of transition between the distance and near portions of the lens. The discontinuity of the image produced at the line between the distance and the near portion of the lens is called “image jump.” The degree of image jump is a function of the power of the reading add and of the distance between the optical center of the reading add and the top of the reading segment. By Prentice rule, discussed earlier in this volume, the amount of prism induced at the top of the bifocal segment is proportional to the distance between the optical center of the segment and the top of the segment. Round-top bifocals have the largest distance between these two points and therefore will produce the largest image jump for any given bifocal power. Traditional flat-top bifocals have only a small distance between the optical center and the top of the bifocal segment and produce only a very small amount of image jump.

Although image jump may be annoying to patients, it is not the chief determinant in choosing the appropriate bifocal segment design. Rather, the bifocal design is chosen in an effort to minimize the total amount of prismatic power induced at the bottom of the patient’s spectacle. All spectacles, even those without bifocal segments, demonstrate prismatic power for all locations away from the optical center. The amount of prismatic power at the bottom of the spectacle lens is important because the shift in the image induced by this prism may cause patients to miss obstacles on the ground or misjudge the location of curbs or steps. It is advantageous to choose a bifocal design that will incorporate a prism of opposite orientation to that already existing in the patient’s spectacles. In the case of hyperopic patients who are wearing spectacles that already incorporate a base up prism in the bottom portion of the lens, the appropriate bifocal choice would be one that demonstrates a base down prism (Figs. 2.4.3 and 2.4.4). This is necessarily a round-top bifocal segment. Such a choice will minimize the total prismatic power at the bottom of the patient’s spectacles and make it less likely that the patient will miss obstacles in his path. Keep in mind that this is the appropriate choice despite the fact that round-top bifocals produce more substantial image jump than flat-top type bifocals.

In the case of the myope who demonstrates a base down prism in the bottom portion of her or his spectacle lens, a base up bifocal design will prove complementary, and therefore a flat-top bifocal is the appropriate choice for this patient (Figs. 2.4.5 and 2.4.6).

Currently, choices exist beyond simple round-top and flat-top designs. Some flat-top shaped bifocals known as C-designs and D-designs actually extend above the optical centers of the reading segment. This results in only a small amount of induced prism over much of the area of the bifocal segment. Therefore this may be an acceptable design even in the case of hyperopic patients. It must be remembered that although this design does not make the image displacement produced by the total prism materially

worse, the choice of this type of bifocal represents a missed opportunity to make the image displacement better.

## Progressive Spectacles

Progressive spectacles or progressive-addition lenses (PAL) hold a number of advantages over traditional bifocal and trifocal lenses. PAL spectacles appeal to patients because they are without visible lines and so do not

**Fig. 2.4.4 The Round-Top Bifocal Segment Increases Image Displacement in Myopic Spectacles.** (Courtesy Joshua Young.)

**Fig. 2.4.5 The Flat-Top Bifocal Segment Decreases Image Displacement in Myopic Spectacles.** (Courtesy Joshua Young.)

Fig. 2.4.7 Parts of a Progressive Addition Lens (PAL). (Courtesy Joshua Young.)

reveal that the patient is of presbyopic age. The lenses have several functional advantages as well. Because no discrete interface exists between the distance and near portions, no image jump occurs. Image displacement is not an independent variable in this type of lens design, and so no choices need be made by the prescribing physician to minimize image displacement either. Progressive lenses incorporate variable dioptric power between the distance portion in primary and upgaze and the reading portion at the bottom of the lens. Because the lens powers are graduated, there is at least some portion of the spectacle lens that will bring objects at intermediate distance into focus.<sup>5</sup>

Progressive lenses vary substantially in design, but all share a number of features. From primary gaze through the center of the lens to the top of the frame, progressive lenses provide a single correction for distance vision. The bottom of the lens contains a region of single power for reading. These two regions are connected in a narrow-waist corridor. The regions to the right and left of the corridor (looking down and to either side) do not provide clear focus at any distance because of the aberrations necessary to produce the graduated power along the centerline of the lens. These afocal areas are called blend zones and are the source of complaints from patients who find it difficult to adapt to progressive lenses (Fig. 2.4.7).

The width of the corridor and the amount of the lens devoted to intermediate vision vary by the particular lens design and manufacturer. Because sufficient room in the spectacle frame must exist beneath primary gaze for the graduation to incorporate an adequate reading portion, some frames are unacceptably short for the incorporation of a progressive lens.

## Occupational Bifocals

Before the advent of desktop computers, bifocal spectacles were probably adequate to most patients' needs. The distinguishing feature of desktop computers is that their screens represent an intermediate distance task that is performed in primary (i.e., straight-ahead) gaze or slightly below primary gaze. Because it is impossible to prescribe spectacles that have two different prescriptions in primary gaze, dedicated computer glasses are often warranted. Progressive spectacles may provide a useful solution if the computer screen can be placed so as to intercept the zone of intermediate-add correction. If the screen is placed too high for the patient to view the computer screen, he must adopt a chin-up position. This is inadvisable for lengthy computer use.

Another solution is to prescribe either single-vision spectacles for the computer distance—often 21 or 22 inches from the patient's eyes—or to prescribe glasses that are indeed bifocal but incorporate only the computer distance and reading distance without having any portion dedicated to far distance vision. These are called occupational bifocals and allow the patient to see the computer screen in primary gaze and to bring printed copy to the closer reading position in downgaze.

## Pantoscopic Tilt and Wrap Angle

In the course of normal activities, people tend to employ either primary gaze or downgaze. Few of our tasks require substantial upgaze. If spectacle

lenses were oriented in the horizontal or coronal plane, the spectacle lens would be farther from the eye in downgaze than in primary gaze. To compensate for this, spectacles incorporate a tilt to the lens about the horizontal axis. This pantoscopic tilt keeps the vertex distance (the distance between the cornea and the lens) more consistent in primary and downgaze. An additional benefit is that the patient gains a larger field of vision in the reading portion of the lens because it is closer to the eye. A similar tilt may be incorporated along the vertical axis. This is referred to as Z-tilt or as the wrap angle of the lens.

## Base Curve and Center Thickness

A number of other variables influence the degree of magnification produced by spectacle lenses. Because myopic spectacles induce a degree of minification, parameters such as base curve (or back curve) and center lens thickness may be altered to reduce this minification. Increasing the convexity of the back surface of the lens and increasing the thickness of the center of the lens will produce a small degree of magnification. In practice, these may be difficult to implement because increasing the thickness of the already thick lens of a high myope will make the spectacle heavy and less attractive and because increasing the back curve tends to increase the vertex distance of the lens.<sup>6a</sup>

## CONTACT LENSES

Although the idea of contact lenses dates at least to a sixteenth-century suggestion by Leonardo da Vinci, it was not until 1887 that a wearable contact lens was developed. This lens, made of blown glass, was much larger than the majority of modern contact lenses and was tolerated for no more than a couple of hours at a time.

Contact lenses of a modern design were introduced in the late 1940s and were made of polymethyl methacrylate (PMMA). These hard contact lenses are still encountered in clinical practice, but the majority of patients who report wearing "hard contact lenses" are not wearing these oxygen impermeable plexiglass lenses but rather lenses of rigid gas permeable material. Beginning in the 1970s, rigid gas permeable lenses were introduced. Soft hydrogel contact lenses were developed in the 1960s and newer silicone hydrogel contact lenses in the late 1990s.

Contact lens wear is associated with a number of risks and hygiene requirements that are more burdensome than simple spectacle wear.<sup>6b</sup> These risks will be discussed later in this chapter, but it bears discussing the advantages to contact lenses that offset these risks and cleaning requirements. The cosmetic advantage of forgoing spectacles is the most obvious benefit to contact lens wear, but several optical benefits also accrue. The pincushion and barrel distortions as well as the astigmatic distortions induced by meridional magnification are greatly minimized by the use of contact lenses. Additionally, much more substantial anisometropia is tolerated with contact lens wear than with spectacles. Indeed, aniseikonia that would otherwise prohibit the correction of monocular aphakia is generally tolerated in contact lenses. Symptoms of anisometropic anisophoria resulting from asymmetrical prismatic power induced by Prentice rule are completely negated with contact lens wear because the optical center of the contact lens moves with the patient's eye. Different types of contact lenses hold different advantages, and each major type of contact lens will be discussed in the section that follows.

## Vertex Correction

Because patients are aware that their prescriptions for spectacles do not vary with the type of frame they choose, it is not unreasonable for them to assume that the prescriptions are also identical for contact lenses. This is not the case, primarily because contact lenses are positioned at a different distance from the eye from spectacles. The distance between the correcting lens and the cornea is referred to as the vertex distance, and this distance must be accounted for when the contact lens prescription is given.

As the vertex distance decreases, the myopic correction must decrease as well. In the case of hyperopic patients, the hyperopic correction is higher in contact lenses than in spectacles. Similarly, myopic patients generally will have a contact lens prescription with a lower number than their prescription for spectacles. The difference produced by the change in vertex distance is small for low-to-moderate myopes and at least in theory should yield no difference for myopic or for hyperopic corrections with an absolute value of less than four diopters. In practice, it is generally beneficial to refract the patient with contact lenses on the eye and to adjust the contact lens by the power of this "overrefraction." A number of other parameters

must be considered when prescribing rigid gas permeable contact lenses to account for the effect of the tear lens, the shape of the tear film between the posterior surface of the contact lens, and the anterior surface of the patient's cornea.

## Rigid Contact Lenses

Rigid contact lenses are made from a number of materials, the salient features of which can be distilled into a few characteristics.<sup>7,8</sup> The rigidity of the material plays a major role in the function of the lenses and determines their flexibility and durability. The oxygen permeability or  $Dk$ , where  $D$  is the diffusion coefficient and  $k$  the solubility constant of oxygen in the material, describes the amount of oxygen that can penetrate through the lens to reach the corneal surface. Wetting angle is the angle created by placing a bead of water against a flat surface of the material and measuring the tangential surface of the bead of water to the horizontal surface, describing the tendency for water to spread on the lens surface.<sup>9</sup> A lower wetting angle indicates more spread of water and suggests the lens material will be more comfortable and offer better optics.

Historically, contact lenses were made from PMMA, a hard and durable material that had very low oxygen permeability but offered sharp optics. Beginning in the late 1970s, silicone has been incorporated into contact lens material to increase oxygen permeability through its bulky molecular structure. As such, most rigid gas permeable (RGP) lenses today are made from silicone acrylate, which allows for the required rigidity and durability while facilitating good oxygen permeability. Silicone does have a tendency to be more bioreactive, binding other hydrophobic substances on its surface, including lipid-containing mucus. The addition of fluorine may counteract this tendency and increase biocompatibility while also increasing the gas solubility.

RGP lenses, unlike most soft contact lenses, must be fit to the individual patient's eye, making this a more laborious process. The fit is first optimized with a set of trial lenses and then the power of the lens is further refined. The base curve of the lens retains its shape, and the space between the cornea and back surface of the lens is filled in with tears, creating a tear lens (Fig. 2.4.8). This tear lens can add plus power (when base curve is steeper than cornea curvature) or minus power (when base curve is flatter than cornea curvature). Because the tear film fills in any corneal surface irregularities, rigid contacts correct irregular corneal astigmatism better than soft lenses.

The most common placement position for RGP is apical alignment, in which the upper edge of the lens fits under upper eyelid, allowing lens to move with each blink, minimizing discomfort and circulating tears. Another position, the central fit, may be used instead, where the lens rests at the center of the cornea between upper and lower lids. With this fit, the eyelids strike the lens with each blink, resulting in increased lens sensation. This position is useful for patients who have large interpalpebral openings, astigmatism greater than 1.75 D, and corneas steep in the horizontal meridian.

A few other parameters can affect the fit of RGP lenses. Thickness and peripheral curves are typically standardized by the manufacturer. The edge thickness of the lens can affect positioning. A thicker edge maintains the lens position under the lid in apical alignment, whereas a thinner edge

maintains centration and comfort for central fit. The diameter of the RGP lens is fit usually to 2 mm less than the corneal diameter. Similar to steepening the base curve, increasing the diameter of a lens also will increase the central vault or sagittal depth of the lens. If the lens is fit too tightly, insufficient lens movement will be observed with each blink. The base curve then may be flattened or sagittal depth may be decreased by decreasing the diameter of the lens. Likewise, increasing the diameter or steepening base curve can tighten the fit of a lens that demonstrates excessive movement on blink.

## Special Purpose Contact Lenses

A number of conditions exist for which rigid gas permeable contact lenses may be of benefit and also for which standard rigid gas permeable contact lenses cannot be fit. The most important pathology that presents this clinical scenario is a condition of corneal ectasia called keratoconus. Patients with keratoconus experience thinning and steepening of the cornea with the apex of the steepness often outside of the geometrical center of the cornea. This steepness and asymmetry often make conventional rigid gas permeable contact lenses inappropriate. Special rigid contact lenses are designed to accommodate the conical shape of the pathological cornea. These contact lenses generally are smaller and steeper and more expensive than conventional rigid gas permeable contact lenses.

Patients who have undergone corneal transplantation may have irregular corneas that warrant rigid contact lens correction. These postoperative corneas are sufficiently different in shape from the surgically naïve cornea that conventional rigid contact lenses cannot be fit. Special contact lens fitting techniques are often warranted in this setting.

Although the intention of keratorefractive surgery is to reduce dependence upon external refractive correction, some patients still require spectacles or contact lenses. In the case of myopic keratorefractive surgery, the most common sort, the postoperative cornea is flatter centrally than it is in the midperiphery. This is exactly opposite to the case of the surgically naïve cornea and often requires contact lenses that are flat centrally as well. Such unconventional contact lenses are available and require special fitting techniques.

## Contact Lens Complications

Contact lens wear generally is a safe option but it is not without risk. Corneal pathology is dealt with elsewhere in this volume, but a brief review of contact lens-associated complications is worthwhile. Adverse events associated with contact lenses can be divided into contact lens intolerance and true contact lens complications. Intolerance to contact lenses may be the result of ocular surface disease as is often observed in patients with dry eyes. Patients with substantial atopy are often poor contact lens candidates and can exhibit both exaggeration of pre-existing ocular allergies and *de novo* reactions such as giant papillary conjunctivitis.<sup>3,4,10</sup> Patients with hypoesthesia either from previous injury or insult or as a result of herpetic infection are often poor contact lens candidates.

Genuine complications arising from contact lens wear may be sterile or infectious. Sterile infiltrates of the cornea may arise from hypoxia or immunological reactions to bacterial endotoxins.<sup>11</sup> These sterile ulcers are often difficult to distinguish from true infectious ulcers, and prudence dictates the treatment with antibiotic therapy even if the chief suspicion is that the ulcer is noninfectious. Bacterial keratitis is the most common serious complication arising from contact lens wear.<sup>12</sup> Even though the ulcer may be small, the development of a central corneal scar can produce a debilitating effect on the patient's vision, and the irregular topography that may result after healing of an ulcer may preclude successful spectacle wear. The risk of recalcitrant amoebic keratitis has prompted clinicians to insist that patients avoid exposing contact lenses and contact lens cases to tap water and to avoid at all costs exposure to outside bodies of water such as lakes, streams, and swimming pools.

Contact lenses may also produce transient effects on the cornea. Cornea molding, the deformation of the topography of the cornea, is a transient feature that may be observed in soft contact lens wear and is almost ubiquitous in rigid contact lens wear.<sup>13,14</sup> Patients with underlying corneal disease may experience corneal edema with contact lens wear, and even patients with otherwise healthy corneas may exhibit edema in the context of corneal hypoxia.<sup>15</sup> Chronic corneal hypoxia may induce the formation of corneal neovascularization, a condition called pannus. Pannus and corneal limbal stem cell pathology may be signs that the patient is wearing the contact lens in a manner not tolerated by the eye and that modification or cessation of contact lens wear is indicated.

**Fig. 2.4.8** The Space Between the Cornea and Back Surface of the Lens Is Filled in With Tears, Creating a Tear Lens. (Courtesy Joshua Young.)

## Soft Contacts

Although the practice of contact lens fitting is beyond the scope of this chapter, the differences between fitting soft contact lenses and rigid contact lenses are worth mentioning. In contrast to case of rigid contact lenses, the tear film between the soft contact lens and the cornea is optically neutral. Therefore any astigmatic correction must occur in the contact lens itself. Because the orientation of astigmatism correction is of great importance, toric soft contact lenses are designed with a variety of mechanisms to sustain the correct orientation. These include ballast weighting and lens edge modulation that, in interaction with the lid margin, maintains the appropriate orientation of the lens.

The primary consideration when fitting soft contact lenses is to achieve good approximation to the anterior surface of the cornea while avoiding such tight adherence of the contact lens to the surface of the eye that the contact lens does not move on blink.<sup>16a</sup> Contact lens movement is important to circulate the tear film underneath the contact lens. On the other hand, a contact lens that is too loose is uncomfortable for the patient. A raised edge of such a lens may cause other wear complications.

The primary distinction between different sorts of soft contact lens materials is between hydrogel and silicone hydrogel. The former are older materials and are less oxygen permeable. Although the newer silicone hydrogel contact lenses enable the movement of oxygen through the contact lens, they generally exhibit poorer wetting than older hydrogel materials.

## Contact Lens Correction of Presbyopia

Presbyopia is the condition of loss of accommodation that arises with increasing age. Presbyopia is a result of increasing rigidity of the crystalline lens and of changes in the ciliary body musculature and as such is not directly correctable by any external optical device. Although contact lenses cannot increase the flexibility or the range of accommodation of the presbyopic eye, a number of strategies have been developed to alleviate some of the symptoms of presbyopia. Several multifocal soft contact lenses have been developed using refractive rather than diffractive optics in contrast to the optical strategies developed for intraocular lenses.

Although multifocal contact lenses may provide focus for both distance and near, they do so with compromise to visual function. Patient dissatisfaction with multifocal contact lenses arises chiefly from decrease in optical quality. These lenses necessarily produce stray rays of light as light from distant objects encounters the near portion of the contact lens and vice versa.

An alternative to multifocal contact lenses is to employ a monovision strategy whereby one eye is fit with a distance contact lens and the other eye with a near-focus contact lens. Each of these lenses is monofocal and may be spherical or astigmatic. Although this may seem to be a less physiological approach than multifocal contact lenses that allow for a degree of fine stereopsis, monovision contact lenses are generally tolerated very well. As a rule, the patient's dominant eye is chosen for distance vision and the nondominant eye is set for either an intermediate distance as would be appropriate for use with a computer or for a reading distance requiring more disparity between the eyes.

Ocular dominance may be assessed in a number of ways, but one of the easiest is to cut a small hole in a piece of cardboard and have the patient fixate at an object while holding the cardboard at arm's length. Having the patient bring the cardboard toward the face while maintaining fixation of the object forces the patient to choose one eye over the other, because the cardboard necessarily occludes the fellow eye. Patients perform this task without realizing that they are forced to make a choice between the eyes.

## Orthokeratology

Myopia, or nearsightedness, is the most common eye disorder in the world, affecting over 85% of young adults in some Asian countries, with a natural tendency to progress with rates of 12% in preschool children that increases to over 50% by preteenage years. With high degrees of myopia, there are increased risks of blinding complications including glaucoma, retinal detachment, and myopic degeneration. A variety of interventions have been studied to slow progression of myopia. Although interventions such as undercorrection, bifocals, progressive lenses, and contact lenses likely do not slow progression, several interventions, including atropine eyedrops and orthokeratology, do seem to have some effect in reducing myopic progression.<sup>16b</sup>

Orthokeratology is the use of purpose-made rigid gas permeable contact lenses to temporarily reshape the cornea to reduce refractive errors such as myopia, hyperopia, or astigmatism.<sup>17</sup> Typically worn overnight, these reverse geometry contact lenses temporarily flatten the cornea centrally for myopic patients, which leads to central corneal epithelial thinning and steepening of the midperiphery, which in turn leads to midperipheral epithelial and stromal thickening. This results in correction of central refractive error while leaving peripheral myopic blur that may act to drive slowing of myopic progression. Younger children are often treated with the intention of reducing the axial elongation, but the FDA has not approved its use for this purpose.

Because these lenses are worn at night and do not move on the cornea, most individuals report no significant discomfort while wearing the lenses. However, these same properties create increased susceptibility to infection of the cornea, an especially concerning condition in a young child in whom amblyopia may be induced. In an attempt to mitigate the risk of infection and decreased oxygen tension at night, these rigid contact lenses are made with high DK values close to 100 to allow for more oxygenation.

## INTRAOCULAR LENSES

Intraocular lenses (IOLs) are discussed in the context of cataract surgery elsewhere in this volume, but it is worthwhile to discuss here the role that IOLs play in the correction of refractive errors. IOLs are broadly separated into categories based on their materials and the refractive errors that they correct. IOL materials include PMMA, silicone, and hydrophilic and hydrophobic acrylic.<sup>18</sup> Even within each of these categories, the optical properties of materials produced by different manufacturers vary in important ways. The Abbe numbers, discussed in the section on spectacle materials, vary by material, and this is relevant in the chromatic aberration produced by different intraocular lenses. Similarly, different materials pose different biocompatibility challenges.

Functionally, IOLs can be divided into monofocal, toric, and a variety of presbyopia-correcting designs. In their surgical roles, IOLs are categorized as anterior chamber, iris plane, sulcus lenses, and posterior chamber “in-the-bag” lenses. IOLs are primarily employed in cataract surgery as replacement for the crystalline lens removed during surgery but may also be used in patients who remain phakic, purely for refractive correction. Additionally, more than one IOL may be inserted into a single eye to achieve a particular refractive affect. When a second IOL is placed on top of another IOL, this second lens is referred to as a “piggyback lens.”

## Monofocal Intraocular Lenses

Monofocal IOLs have the broadest range of designs, including lenses designed for anterior chamber placement, sulcus and iris plane placement, piggyback, phakic, and one-piece and three-piece posterior chamber IOLs designed for placement within the capsule bag. Monofocal lenses are also available in spherical and aspherical designs produced to decrease spherical aberration created by the optics of the front of the eye. Monofocal IOLs also hold the advantage of enhanced visual quality compared with the multifocal lenses described later. This is perceived by the patient as higher contrast sensitivity.

An important consideration in choosing the appropriate power of an IOL is its intended postoperative location within the eye. This is referred to as the effective lens position or ELP.<sup>19</sup> As is the case with contact lenses described earlier, the anteroposterior position of the IOL changes its refractive effect. To achieve the same refractive effect, lenses with a more posterior position require higher plus dioptric powers. This is important clinically not only in the context of preoperative IOL calculation but in the event that the surgeon chooses to place a lens in the ciliary sulcus that was originally intended for placement within the capsular bag. This contingency may arise in the context of certain surgical complications, most commonly rupture of the posterior lens capsule.<sup>20</sup>

## Toric IOLs

Pre-existing astigmatism may be addressed during cataract surgery by incisional keratotomies, described elsewhere in this chapter, and by employing an astigmatism-correcting IOL. These toric IOLs differ from astigmatism-correcting contact lenses in that they incorporate no special elements to establish the orientation of the lens. Therefore IOLs are produced in different spherical and astigmatic powers but not in different axes. The axis of orientation is of great import to achieve the desired refractive result,<sup>21</sup> and many methods—from marking the cornea with a pen to

automated computer-based corneal registration—have been employed to ensure the appropriate toric IOL orientation.

Although toric are of immense value in clinical practice, their benefit is contingent on a number of factors.<sup>22</sup> Typically, the astigmatism of a nonoperated eye is primarily of corneal origin. However, the crystalline lens may itself be tilted, and this lenticular astigmatism is not amenable to correction with a toric IOL. Irregular astigmatism also is not completely correctable with a toric IOL, and caution must be exerted when employing a toric IOL in the context of keratoconus.

Even small misorientations of a toric IOL can produce clinically significant diminutions of the ability of the IOL to correct the patient's astigmatism. Each degree of misorientation will produce a diminution of effect of 3.3% and a rotation of the patient's axis of astigmatism. A misorientation of 30° completely negates the reduction of absolute astigmatism while simultaneously rotating the astigmatic axis to an orientation to which the patient is unaccustomed.

## Presbyopia Correcting Intraocular Lenses

Because presbyopia is the result of loss of accommodation, the obvious surgical solution would be the implantation of an accommodating intraocular lens. Such accommodating intraocular lenses are in clinical trials, but no truly accommodating intraocular lens has been approved to date for clinical use in the United States.

A number of alternatives to this ideal are available. It must be remembered that in addition to the out-of-pocket cost associated with these premium lenses, there is an optical cost that must be paid to achieve both distance and near vision. The first and optically simplest manner in which to address presbyopia during cataract surgery is to employ monofocal IOLs in a monovision strategy as is discussed in the section on contact lens correction of presbyopia.<sup>23</sup> Of course, a risk of this strategy is that the patient may not tolerate monovision or may only tolerate the degree of monovision that allows for intermediate (e.g., computer) use and does not yield the ability for closer reading without spectacles. The advantage of this strategy is that contrast sensitivity and overall visual quality is not diminished in either eye individually.

Multifocal IOLs are designed to project both distance and near images onto the patient's retina.<sup>24</sup> This is generally done by employing a refractive lens for the distance focus and a diffractive lens for reading (Fig. 2.4.9). The combination of refractive and diffractive elements holds the advantage of decreasing the overall chromatic aberration because short wavelength light converges to a greater degree than long wavelength light in refractive lenses, and the opposite is true in diffractive lenses. However, the rings employed in diffractive designs cause visual symptoms that disturb some patients.<sup>25,26</sup> Also, visual quality is poorer in multifocal lenses than in monofocal spherical or toric lenses. The degree to which these visual degradations are tolerated is impossible to predict preoperatively with certainty, and a higher number of multifocal lenses require explantation for reason of bothersome visual symptoms than is the case with monofocal IOLs.

**Fig. 2.4.9** A Type of Multifocal Intraocular Lens (IOL) With Refractive and Diffractive Elements. (© 2017 Novartis.)

Lenses designed to demonstrate functional vision over a range of distances have been introduced recently. These are generally referred to as extended depth of focus (EDOF) lenses. Although these lenses may provide a more uniform visual quality between far and intermediate distances, the visual quality is diminished across all distances compared with monofocal IOLs.

An early attempt to design an accommodating IOL was approved for clinical use in the United States.<sup>27</sup> However, this design yields insufficient presbyopia correction to replace reading glasses and is often referred to as a “pseudoaccommodative intraocular” lens.

## KERATOREFRACTIVE SURGERY

The idea of refractive surgery is not a new one and dates to at least the late nineteenth century. Although refractive surgery may be undertaken to any of the optical surfaces of the front of the eye, the most fruitful approach has been the intentional modification of the shape of the cornea. The anterior surface of the cornea accounts for the great majority of the refractive power of the eye, and fractional modification of the surface curvature may produce tremendous refractive change.

Discussion in this section will center on corneal refractive surgery or keratorefractive surgery, but it bears mentioning that intraocular refractive surgery also is performed. Removal of the noncataractous crystalline lens and replacement with an IOL—so-called clear lens extraction—may be performed successfully for higher refractive errors at the expense of the loss of accommodation. This procedure is identical to conventional cataract surgery. Additionally, an IOL may be inserted into the eye without removal of the patient's own crystalline lens. This is referred to as phakic lens implantation or implantable collamer lens (ICL) surgery.<sup>28-31</sup>

The majority of patients who undergo refractive surgery are undergoing some modification of the shape of the anterior cornea. Initially, this was performed by making incisions in different patterns on the corneal surface. Radial incisions in the cornea cause circumferential flattening. Thereby myopic correction is achieved through the creation of a series of radial incisions centering about the central cornea but, of course, not passing through the corneal center. This is the basis of radial keratotomy, a procedure that can successfully correct substantial degrees of myopia<sup>32</sup> (Fig. 2.4.10). Although nomograms were developed for titratable correction of various degrees of myopia, radial keratotomy incisions proved to have an unstable effect for many patients over the long term. Patients who were initially corrected to emmetropia sometimes demonstrated a progressive increase in the degree of corneal flattening over many years postoperatively. These formerly myopic patients experience a trend toward increasing hyperopia over time.<sup>33</sup> Radial keratotomy also carries the additional concern of globe rupture with blunt trauma, even years after the surgery, because the structural integrity of the cornea has been violated and never completely recovers.

In a manner similar to the myopic correction achieved by radial keratotomy, astigmatic correction is achievable through tangential or arcuate incisions of the midperipheral or peripheral cornea. These incisions need

**Fig. 2.4.10** In Radial Keratotomy (RK) Surgery, Flattening Perpendicularly to the Radial Incisions Reduces the Average Refractive Power of the Cornea and Corrects for Myopia. (Courtesy Joshua Young.)

not be made as deep, and are generally fewer in number than those of radial keratotomy and so pose less of a structural risk to the eye. In the past, radial and arcuate incisions were combined to correct for myopic astigmatism.

Although radial incisions have largely been displaced by laser ablative surgery as discussed later, arcuate incisions continue to play a role for correction of low degrees of astigmatism during cataract surgery. Arcuate keratotomy has morphed into the limbal relaxing incisions (LRI) performed during cataract surgery.

Historically, myopic correction could be performed by the removal of a lenticule of corneal stromal tissue. This was performed using a motorized blade in a miniaturized device looking something like a wood plane. Automated lamellar keratectomy, ALK as it was called, formed the mechanical foundation of the microkeratome, the device created to produce corneal flaps for laser in situ keratomileusis (LASIK) surgery.

Incisional keratotomy may correct myopia and astigmatism, but the correction of hyperopia is not achievable in this manner. In order to steepen the central cornea, surgeons sought to create a zone of contraction of corneal tissue paracentrally. One approach to this was conductive keratoplasty (CK), in which heating was induced focally in a number of spots surrounding the center of the cornea.

In the mid-1990s, the excimer laser was introduced to clinical practice to perform athermal ablation of corneal tissue to reshape the cornea to produce the desired refractive effect. Excimer ablation holds the advantages of great precision without substantial compromise to the mechanical integrity of the cornea. However, ablation through the anterior layers of the corneal stroma, termed Bowman's layer, resulted in the creation of symptomatic corneal haze in some patients. Today this haze may be dealt with by using mitomycin C to modulate postoperative healing or may be avoided altogether through the creation of an anterior corneal flap under which the laser treatment is performed. The combination of ablation plus a flap is what it has been termed laser in situ keratomileusis. LASIK flaps may be produced by means of femtosecond laser rather than by mechanical microkeratome. The advantages of the flap are faster visual recovery, less corneal haze, and greater patient comfort. The disadvantage of the flap is that adhesion of the flap to the underlying cornea is not as strong as the shear resistance of the surgically naïve corneal tissue. Therefore even very late term shear stress, such as may be experienced with ocular injury, can dislodge a LASIK flap.

Although ablative keratorefractive surgery carries risk, it must be remembered that contact lens wear also carries risk that is cumulative over the many years a patient may wear contact lenses. For many patients, the risk of a keratorefractive procedure is comparable to the risk of contact lens wear and represents an acceptable alternative.

Both spherical errors and astigmatic errors are correctable with ablative keratorefractive surgery. Different refractive errors are corrected by altering the ablation pattern.<sup>34</sup> The correction of myopia is achieved by the simple ablation of a lenticule from the center of the cornea. Because tissue cannot be added by the excimer laser, however, steepening the central cornea as is required for the correction of hyperopia necessitates a more complicated ablation pattern. A torus (think of a doughnut or bagel sliced in half) is ablated from just outside of the center of the cornea to produce steepening centrally. However, the zone of uniform curvature, the optical zone, is necessarily smaller in a hyperopic treatment than in a myopic treatment.

The femtosecond laser may be used to carve a lenticule from the central cornea in a manner reminiscent of automated lamellar keratectomy. This lenticule is then withdrawn through a channel also carved into the cornea by the femtosecond laser. This procedure is known as small incision lenticule extraction or SMILE surgery and is relatively new.

## CORNEAL INLAYS

While the correction of presbyopia is not directly achievable by means of refractive surgery, a number of procedures have been introduced to alleviate some presbyopia symptoms. These procedures have in common the introduction of an implant into the substance of the cornea. Two corneal

**Fig. 2.4.11 The KAMRA Inlay Implanted Within the Cornea to Alleviate Symptoms of Presbyopia.** (December 2016 EyeWorld REFRACTIVE SURGERY section.)

inlays approved for use in the United States are the KAMRA and the Raindrop devices. The KAMRA inlay is a small opaque disc with an even smaller aperture in the center that functions as a as an optical pinhole. This inlay increases depth of field while reducing the amount of light that enters the eye. This increase in depth of field gives patients some degree of near vision. The KAMRA inlay is implanted in only one eye<sup>35</sup> (Fig. 2.4.11).

The Raindrop inlay is no longer available as of publication. It is a small clear lenticule and is also implanted in only one eye. Corneal inlays are introduced underneath a corneal flap or in a corneal pocket and sit within the corneal stroma.<sup>36,37</sup>

**Definition:** From the earliest optical devices to the latest computerized imaging systems, technology has aided the clinician in the diagnosis and treatment of ocular disease.

## Key Features

- The ability of a transparent medium to bend a ray of light is the basis for most of the instruments used in ophthalmology today.
- Spherical lenses, prisms, mirrors, slit-shaped illumination, astronomical and Galilean telescopes, and a multitude of other optical components—both simple and complex—have been devised and manufactured for more than two centuries in order to study the human eye and its function.

## INTRODUCTION

In this chapter, the basic principles that underlie some of the more common instruments used in ophthalmology will be reviewed, including:

- Direct ophthalmoscope.
- Binocular indirect ophthalmoscope.
- Fundus camera.
- Optical coherence tomograph.
- Slit-lamp biomicroscope.
- Slit-lamp fundus lenses.
- Goldmann applanation tonometer.
- Specular microscope.
- Operating microscope.
- Keratometer and corneal topographer.
- Lensmeter (also known as lensometer).
- Automatic refractor.
- Magnifying devices.

## DIRECT OPHTHALMOSCOPE

The entire retina, if spread out and flattened, is about the size of a large postage stamp. The important structures themselves are rather small. For example, the optic nerve is 1.5 mm in diameter, and the major blood vessels are only 0.1–0.2 mm in diameter. Significant papilledema, with an elevation of the nerve head of 3.00 D, is equivalent to only a 1 mm change in elevation. Most of the important red and yellow details, including blood vessels, hemorrhages, and exudates, are seen against the light red background of the blood-filled choroid. Subtle changes in the pinkish white backscattered light of the optic disc announce major glaucomatous or neuro-ophthalmic alterations. The presence of the corneal reflection and the usual backscattered light of the healthy cornea and lens make the evaluation of fundus changes even more difficult.

In the face of these obstacles, it seems almost miraculous that the examiner is able to make a significant number of diagnoses using the direct ophthalmoscope. Fig. 2.5.1 illustrates how the ophthalmoscope directs the light rays of illumination and observation coaxially, while the observation system is essentially a peephole.<sup>1</sup> The lens and cornea of the patient's eye actually create the retinal image. Thus the observer does not really see the retina of the patient but an optical image of the retina.

To bring the red fundus reflex into sharp focus for the viewer, the modern ophthalmoscope has a disc of lenses. Because the compensating lens neutralizes the refractive error of both the physician and the patient

and the accommodation of each, its total power provides only a rough estimate of the patient's refractive state. The magnitude of a large amount of astigmatism may actually be estimated if the lens is focused on a blood vessel that travels parallel to the foveal reflex and then refocused on a vessel that travels perpendicular to the first vessel.<sup>2</sup>

Probably the most important advance in direct ophthalmoscopy was the use of the halogen tungsten bulb,<sup>3</sup> which has a number of advantages over the older tungsten bulb. A quartz jacket can withstand higher temperatures than can the glass jacket, thus the filament temperature may be raised higher than that in the conventional tungsten bulb to produce an increased lumen output.

The field of view of the modern direct ophthalmoscope averages about 10° and is limited by the most oblique pencil of rays that can pass from the outer edge of the observer's pupil to the opposite outer edge of the patient's pupil. To enlarge the field of view of the direct ophthalmoscope, the investigator's eye must be brought closer to the patient's eye with the patient's pupils dilated.

Because the enlargement capacity of any magnification lens usually is defined as one-fourth of the lens power, the retinal image in the typical emmetropic eye of 60 D may be considered to be magnified by 60/4, or  $\times 15$ . In aphakic eyes, from which a 20 D natural lens has been removed, the magnification for the observer is reduced to about 40/4 or  $\times 10$ .

## BINOCULAR INDIRECT OPHTHALMOSCOPE

Compared with the direct ophthalmoscope, the binocular indirect ophthalmoscope gives a wide field of view, a stereoscopic impression, and an image of high contrast. Of course, a small price must be paid for these advantages. The patient's pupil must be dilated, the instrumentation is larger, heavier, and more expensive, and the illumination is almost painfully bright for the patient.

## Illumination System

In order to avoid corneal and lens reflection and scatter, the observation beam and the illumination beam is separated at the corneal and lens plane,<sup>4</sup> requiring a dilated pupil (Fig. 2.5.2). The filament of the bulb is actually brought to a focus in a portion of the patient's pupil. To minimize the loss of light, the condenser lens brings the observer's pupil to a focus

**Fig. 2.5.1 Optics of the Direct Ophthalmoscope.** With use of a mirror (either half-silvered or one that has a central aperture), the directions of the light of observation and the light incident to the patient are made concentric (coaxial).

**Fig. 2.5.2 Theoretical Optics of the Indirect Ophthalmoscope.** The illumination beam enters a small part of the pupil and does not overlap with the observation beam, and thus minimizes bothersome reflection and backscatter.

**Fig. 2.5.3 Field of View, Indirect Ophthalmoscope.** The focal length of the handheld lens determines the distance from the patient's eye at which to hold the lens. The tangent of the angle of field of view equals the lens diameter divided by the focal length.

in the patient's pupil. With patient and observer pupils conjugate, loss of light is minimized, and field of view is maximized.

## Observation System

### Contrast

Because the observation beam path is different from the illumination beam path, glare degradation from reflection and backscatter is minimized and subtle details are seen more easily. The observer must learn to tilt the handheld lens strategically to avoid reflection from the surface of the lens itself. This reflection is minimized (from about 4% of incident light to 1%) by a lens that has an antireflection coating.

### Inverted Image

The handheld condenser lens creates a real, inverted aerial image of the illuminated patient's fundus, as expected from a positive lens. Thus the examiner must learn to reorient details from where they appear to be to where they actually are located.

### Field of View

Fig. 2.5.3 illustrates how the handheld lens produces the aerial image of the fundus. Rays that pass through the nodal point of the patient's eye and the edge of the handheld lens determine the size of the field of view. The distance of the handheld lens from the patient's eye also determines the angular subtense of the patient's fundus caught by the lens. This distance is optimal if it equals the focal length of the lens. Thus the field of view is determined by the expression  $d/F$ , where  $d$  is the diameter and  $F$  the focal length of the handheld lens.

For example, given equal diameters, stronger lenses (e.g.,  $F = 30$  D,  $f = 3.3$  cm) provide larger fields of view. However, a weaker lens may be made with a larger diameter because it is less vulnerable to spherical aberration.

**Fig. 2.5.4 Zeiss Fundus Camera.** See text for the description. (Adapted from American Academy of Ophthalmology. Home study course, optics and refraction. San Francisco, CA: American Academy of Ophthalmology; 1990.)

Thus a 20 D lens of 3 cm diameter yields almost the same field of view as a 30 D lens of 2 cm diameter.

### Magnification

Fig. 2.5.3 shows the chief ray that passes from the edge of the fundus view through the nodal point of the eye to the aerial image. The ratio of the fundal object to the aerial image is proportional to the ratio of the focal length of the patient's eye to the focal length of the condenser lens, or inversely proportional to the power ( $F$ ) of the eye (60 D) and the handheld lens. Thus for an emmetropic eye and a 20 D lens, the magnification =  $60 \text{ D}/20 \text{ D} = \times 3$ ; for a 30 D lens, the magnification =  $60 \text{ D}/30 \text{ D} = \times 2$ .

Ultimately, the distance of this mildly magnified aerial image from the observer determines the total magnification. If the observer has a large amplitude of accommodation, the aerial image is brought closer and its overall magnification increased.

### Stereopsis

The light beam that emerges from the patient's dilated pupils is directed through the handheld lens and into the two eyepieces (separation usually 15 mm) of the binocular indirect ophthalmoscope. Prisms then redirect the two beams into the examiner's eyes. A smaller distance between the two eyepieces than the interpupillary distance reduces the stereopsis appreciated by an observer (interpupillary distance of 60 mm) by about one-fourth. However, axial magnification (which equals one-fourth of the square of lateral magnification) augments the stereoscopic appearance. If the lateral magnification of a 20 D lens is  $\times 3$ , the axial magnification equals  $9/4$  or  $\times 2.25$ . Thus the ophthalmoscopic view through the handheld lens amplifies small changes in retinal topography. Using a lower power hand lens further increases this effect: for example, a 15 D lens results in transverse magnification of  $60/15 = 4\times$ , but axial magnification of  $16/4 = 4$ -fold.

Variations of indirect ophthalmoscopy include the scanning laser ophthalmoscope and various analyzers of the optic nerve head.

## FUNDUS CAMERA

### Lighting

The present illumination system of the Zeiss fundus camera is shown in Fig. 2.5.4.<sup>5,6</sup> Light from the incandescent lamp (for observation) and the flash lamp (for photography) is superimposed by means of the beam splitter, so that the light from the flash travels along the same path as that of the observation light. The lamp filaments are imaged in the vicinity of the holed mirror, which deflects the light toward the eye. The holed mirror is similar to the mirrors used in many retinoscopes, with a central hole to allow observation. In contrast to the retinoscope arrangement, the holed mirror in the fundus camera is imaged onto the plane of the patient's

pupil by the objective lens to ensure the necessary separation of illumination and observation pathways at the pupil. The objective lens corresponds to the condenser lens in the indirect ophthalmoscope; both lenses are designed with aspherical surfaces to provide the best possible image quality over a wide field of view.

Photographing through an undilated pupil was achieved by observation of the fundus using infrared light, which does not stimulate the retina. In such a system, the infrared light penetrates the 4–5 mm diameter pupil in a dark setting, is reflected off the retina, and is displayed on a monitor. Once the retina has been focused and framed, an electronic flash illuminates the retina before the pupil constricts.

## Reducing Reflections From the Cornea and Instrument

Anyone who has tried to evaluate subtle macular detail using a direct ophthalmoscope is familiar with the annoyance of corneal reflection. Gullstrand's table-mounted ophthalmoscope embodied his principle that the illumination system should not intersect the cornea in the same area as the rays that come from the observation system. In the Zeiss system, this principle is satisfied by a mirror that has a central hole. The mirror reflects a circle of light through the pupillary periphery while the fundus is viewed through the central hole of the mirror. Although such a system is not able to completely eliminate ocular and camera lens reflections, it successfully reduces them to a significant degree.

## The Observation System

Fig. 2.5.4 illustrates all the elements of the fundus camera. As noted before, light from the incandescent lamp and that from the flash lamp are folded into a common path, which ultimately strikes the holed mirror and is reflected into the patient's eye. This illumination system and the observation system are very similar to those of the indirect ophthalmoscope. In the case of the fundus camera, light reflected from the patient's retina passes through the hole in the mirror and focuses a real image in the film plane of the camera. A beam splitter diverts a portion of the light directed to the camera and sends it to the eyepiece. In essence, the eyepiece is like a simple microscope. It receives the real image of the fundus and processes it such that parallel light exits for the observer.

## Field of View

In theory, a 180° aerial image of the retina can be captured, even through a small pupil. In practice, however, because the rays from the equator exit the pupil at a very sharp angle, the collection of these rays can be accomplished only by a lens held very close to the pupil or a lens of very wide diameter. Of course, although wide-diameter lenses produce a greater field of view, they also introduce significant spherical aberration. For fields of view greater than 100°, therefore, the only sensible way to collect the sharply bent rays that come from the retinal periphery is to move the front lens close to the pupil. Thus in the equator-plus camera, the front lens of the system is a contact lens. Because the aerial image of such a large expanse of retina follows the globe's curvature, special lenses must be introduced into this system to flatten the image.

To photograph different fields of view, three different focal length lenses are used, much as the ophthalmologist might switch between +14 D, +20 D, and +28 D handheld lenses. The lens system that has the longer focal length (less dioptric power) produces a more magnified image. Thus the amount of field captured in a frame is smaller than that produced by the more powerful, shorter focal length lens. Theoretically, both the larger field and higher magnification could be obtained if the size of the film could be doubled.

Portions of the retina can be photographed beyond the traditional central 30° if the camera is directed to the peripheral area of interest. However, a camera aimed off axis by 30° or more with the 60 D ocular optical system induces 10–15 D of oblique astigmatism and results in fuzzy pictures.<sup>7</sup> Fortunately, well-designed fundus cameras anticipate off-axis photography and include a large range of cylindrical corrections with which to sharpen the peripheral views.

## OPTICAL COHERENCE TOMOGRAPHY

Optical coherence tomography (OCT) is based on the Michelson interferometer invented in the late 1800s. Originally the instrument was used to make extremely accurate measurements of length. A single beam of

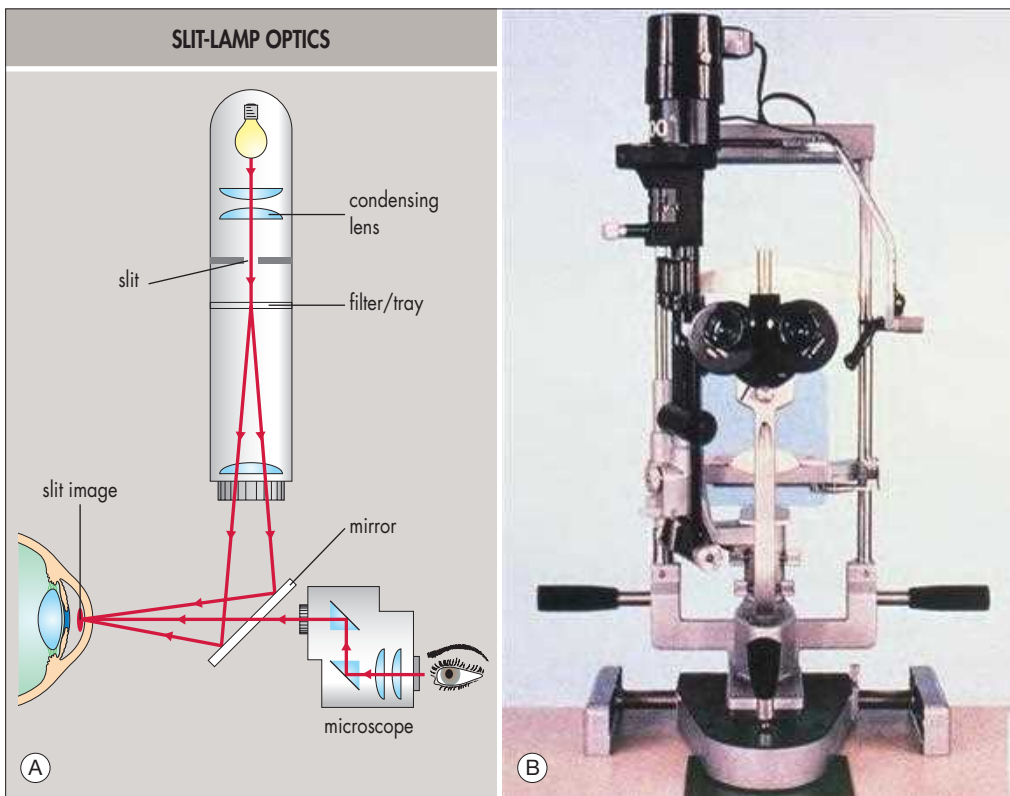

**Fig. 2.5.5 Optical Coherence Tomography (OCT).** Based on the principle of the Michelson interferometer, OCT analyzes the interference patterns between a reference beam and the object beam to create a precise cross-sectional reflectivity map of the internal retina.

white light is split into two beams moving in perpendicular directions. The beams are reflected back to, and recombine at, the beam splitter. When the beams recombine, interference fringes are observed, provided that the difference in optical path length (OPL) between the two arms of the interferometer is less than the coherence length of the light utilized. Michelson used white light with a coherence length of 1–2  $\mu\text{m}$ . One arm of the device had a fixed, known length, and the length of the other arm was varied until interference fringes were observed, at which point the difference in OPL between the two arms had to be less than 2  $\mu\text{m}$ . Submicron accuracy could be achieved by counting fringes.

If this technique were directly applied to retinal imaging, only a single layer's thickness could be measured because of the low coherence of white light. However, if a laser is used, the coherence length is too long and the position of a retinal layer could be localized only to within a few centimeters. The OCT utilizes a superluminescent diode that operates in the near-infrared and has a bandwidth of about 50 nm or about six times more coherent than white light but far less than the coherence of a laser.

The original clinical instruments incorporated two moving mirrors. One varied the length of one arm of the interferometer and was used every time the device scanned a narrow section of retina (Fig. 2.5.5). After a single scan was completed, the other mirror shifted the beam to the neighboring section of the retina and the next scan was repeated. An important limitation was the amount of time required to complete a scan. The time required to scan a single line of retina a few millimeters in length far exceeded even the best patient's fixation. Moreover, the eye itself is not dimensionally stable due to choroidal blood flow that varies with the cardiac cycle. Sophisticated software can overcome some fixation requirements, but limitations exist to this technique.

In spectral domain instruments one of the mirrors (which scans the reference arm) is replaced by a spectrometer that measures the reflection from each wavelength simultaneously, producing a much faster scan that not only improves accuracy but also enables a larger region of retina to be interrogated. It is important to realize that OCT measures optical path length not physical thickness. The presence of edema or other pathologies

**Fig. 2.5.6 The Slit Lamp.** (A) Some slit lamps first bring the light to a sharp focus within the slit aperture, and the light within the slit is focused by the condensing lens on to the patient's eye. The observation system of a modern slit lamp has many potential reflecting surfaces; antireflection coatings on these surfaces help reduce loss of light. (B) Slit-lamp apparatus. (Modified from Spalton DJ, Hitchings RA, Hunter PA. *Atlas of clinical ophthalmology*. New York: Gower Medical; 1984. p. 10.)

that differ in refractive index from the retina can distort the apparent thickness of the pathology, leading to imaging artifacts that can complicate interpretation of OCT images.

## SLIT-LAMP BIOMICROSCOPE

The slit lamp is the piece of equipment most frequently used by the ophthalmologist.<sup>8</sup> With the addition of auxiliary lenses, it can give unique, magnified views of every part of the eye. In conjunction with auxiliary devices it can be used to take photographs and to make quantitative measurements, including intraocular pressure, endothelial cell counts, pupil size, corneal thickness, anterior chamber depth, and others.

## Illumination

The modern slit lamp produces an intensity of about 200 mW/cm<sup>2</sup>. When operated at the rated voltage, halogen lamps have a higher luminance and color temperature than do conventional incandescent lamps. For slit-lamp work, a high color temperature (e.g., a greater amount of blue light) is useful. Because many of the ocular structures are seen via light scatter, and because the shorter wavelengths are scattered most, a light with a high blue component illuminates the structures best. The light is first brought to a focus at the slit aperture (Fig. 2.5.6), and the light within the slit is focused by the condensing lens onto the patient's eye.

## Improving Tissue Contrast

One of the great strengths of the modern slit lamp is the way in which contrast can be improved by various maneuvers:

- **Optical sectioning:** As the beam is narrowed, the scattered light of adjacent tissue is removed and greater detail of the optical section is seen.
- **Tangential illumination:** When the light is brought in from the side, highlights and shadows become stronger, and the texture (i.e., elevations and depressions) is seen better.
- **Pinpoint illumination:** The cells and flare in the anterior chamber in a patient who has iritis are best seen using a narrow beam focused into the aqueous, so that the black pupil becomes the background. The combination of the narrow beam and the dark pupillary background eliminates any extraneous light that would reduce contrast. The same principle holds when the examiner pushes the lower lid up to examine the tear meniscus. For example, the stagnant cell pattern of an obstructed tear duct is best seen using a narrow beam with the dark iris in the background.

- **Specular reflection:** In this technique the angle of observation is set to equal the angle of illumination. In this way, the structure of the front surfaces of the cornea (i.e., ulcers, dry areas) and the rear surfaces (endothelial pattern) may be assessed.
- **Proximal indirect illumination:** In this technique a moderately wide beam is directed to the areas adjacent to the area of interest. Against a dark background, the backscattered light from the lesion yields a higher contrast, which often allows the observer to see the borders of the lesion more precisely. For example, when this technique is used, subtle corneal edema—with its minute pools of fluid—stands out more distinctly against a dark pupil.
- **Sclerotic scatter:** With the slit illuminator offset from its isocentric position, light is directed to the limbus. The light then follows the cornea as if it were a fiberoptic element and reaches the other side of the limbus. However, if a lesion or particles within the cornea exist, the backscattered light from the lesion or particles is seen clearly against the dark pupillary background.
- **Retroillumination from the fundus:** Light sent through the pupil to the fundus is reflected and yields an orange background. Holes in the iris or subtle wrinkles in the cornea become silhouetted and much easier to see.

## Observation System

The observation system of the slit-lamp biomicroscope has a long working distance of about 3.9 inches (10 cm), which is about 100 times longer than that of a laboratory microscope. Prisms take the divergent rays from the patient's eye and force them to emerge as parallel pencils from each eyepiece. Thus a stereoscopic appreciation of the patient's eye is achieved without convergence of the observer's visual axis. Most slit-lamp microscopes offer magnifications between  $\times 5$  and  $\times 50$ , with  $\times 10$ ,  $\times 16$ , and  $\times 25$  being the most popular. Image resolution is ultimately limited by diffraction.

## SLIT-LAMP FUNDUS LENSES

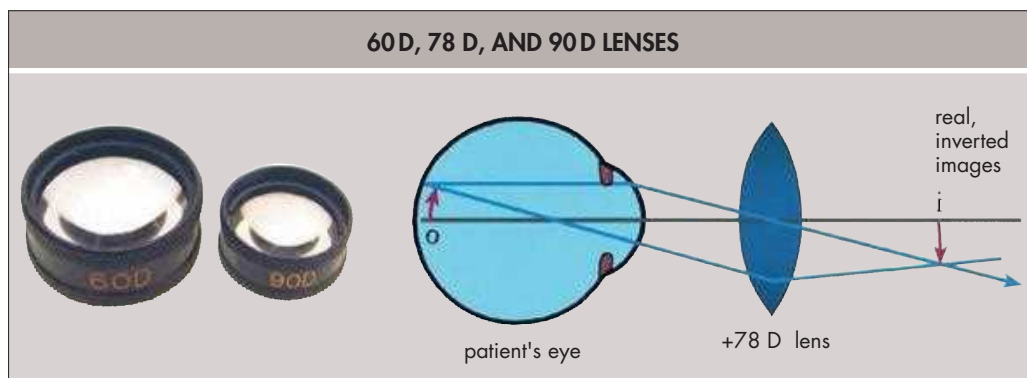

Because the cornea has such a high refractive power, the slit-lamp microscope can view only the first one-third of the eye.<sup>9</sup> Special lenses, in conjunction with the slit-lamp microscope, can be used to view the posterior vitreous and the posterior pole retina. The two ways to overcome the high corneal refractive power are (1) nullifying the corneal power, or (2) utilizing the power of the cornea as a component of an astronomical telescope in a manner similar to that exploited by the indirect ophthalmoscope.

**Fig. 2.5.7** The Goldmann fundus contact lens, or any similar plano-concave contact lens, nullifies the refractive power of the cornea, thereby moving the retinal image close to the pupillary plane and into the focal range of the slit-lamp microscope. The image formed is virtual, erect, and diminished in size.

**Fig. 2.5.8** The concave Hruby lens, when placed close in front of the patient's eye, forms a virtual, erect image of the illuminated retina that lies within the focal range of the slit-lamp microscope.

**Fig. 2.5.9** The 60 D, 78 D, and 90 D lenses produce inverted, real images of the retina within the focal range of the slit-lamp microscope in a fashion similar to that employed by the indirect ophthalmoscope.

The Goldmann contact lens (Fig. 2.5.7) and other similar lenses work in conjunction with the slit-lamp microscope to nullify the dioptric power produced by the corneal curvature and to bring the retina into the focal range of the slit-lamp microscope. These plano-concave contact lenses are placed on the cornea, forming virtual, erect, and diminished images of the illuminated retina near the pupillary plane within the focal range of the slit-lamp microscope.

The Hruby lens is a powerful plano-concave lens,  $-58.6$  D in power. It is held immediately in front of the cornea, forming a virtual, erect, and diminished image of the illuminated retina near the pupillary plane, bringing it within focal range (Fig. 2.5.8).

The 60 D, 78 D, and 90 D fundusoscopic lenses (Fig. 2.5.9) use a different approach to view the posterior vitreous and posterior pole retina. These lenses act as high-powered, biconvex, condensing lenses, projecting an inverted, real image in front of the lens within focal range. This is the same optical principle used by the indirect ophthalmoscope: the higher the power of the lens, the lower the magnification of the image.

The Goldmann three-mirror contact lens (Fig. 2.5.10), as its name implies, incorporates three internal mirrors. The contact lens nullifies the refractive power of the patient's cornea, and the three mirrors then reflect light from the patient's midperipheral retina, peripheral retina, and the iridocorneal angle, respectively. The posterior pole of the fundus can be visualized, also, in a manner similar to that of the Goldmann posterior pole contact lens.

The Quadraspheric, SuperQuad, and similar lenses are corneal contact lenses (Fig. 2.5.11).

A real, inverted aerial image of the fundus is formed a few millimeters outside the large aspherical condensing lens, which is within the focal range of the slit-lamp microscope. Because the condensing lens is so close to the eye and has such a high power, the field of view is very wide, making these lenses specially suited for a wide-angle view of the posterior pole and midperipheral fundus.

## GOLDMANN APPLANATION TONOMETER

The applanation tonometer (Fig. 2.5.12) is used to measure intraocular pressure. It relies on an interesting physical principle. For an ideal, dry, thin-walled sphere, the pressure inside a sphere is proportional to the force applied to its surface. Unlike an ideal sphere, however, the human eye is not thin-walled and it is not dry, producing two confounding forces: (1) a force produced by the eye's scleral rigidity (because the eye is not thin-walled), directed away from the globe; and (2) a force produced by the surface tension of the tear film (because the eye is not dry), directed toward the globe (Fig. 2.5.13). Goldmann determined that when a flat surface is applied to the cornea with enough force to produce a circular area of flattening 3.06 mm in diameter, then the force caused by scleral rigidity exactly cancels out the force caused by surface tension. Therefore it is a very useful fact that the applanating force required to flatten a circular

## EFFECT OF GOLDMANN LENS AND MIRRORS

**Fig. 2.5.10** The contact lens of the Goldmann lens nullifies the refractive power of the patient's cornea, while the three mirrors then reflect light from the patient's peripheral retina (*orange ray*) and iridocorneal angle (*green ray*). The posterior pole of the fundus also can be visualized in a manner similar to that of the Goldmann posterior pole contact lens (*blue ray*).

**Fig. 2.5.11** The QuadrAspheric lens consists of a corneal contact lens and a high-powered, highly aspherical condensing lens. A real, inverted image of the fundus is formed, which is within the focal range of the slit-lamp microscope. (Courtesy Volk Optical.)

area of cornea exactly 3.06 mm in diameter is directly proportional to the intraocular pressure. Specifically, the force (measured in dynes) multiplied by 10 is equal to the intraocular pressure (measured in millimeters of mercury).

How does the observer know when the area of applanation is exactly 3.06 mm in diameter so that the intraocular pressure can be measured? The applanation tonometer is mounted on a biomicroscope to produce a magnified image. When the cornea is applanated, the tear film, which rims the circular area of applanated cornea, appears as a circle to the observer. The tear film often is stained with fluorescein dye and viewed under a cobalt-blue light to enhance the visibility of the tear film ring. Higher pressure from the tonometer head causes the circle to have a wider diameter because a larger area of cornea becomes applanated (*Fig. 2.5.14*). Split prisms, each mounted with their bases in opposite directions, are mounted in the applanation head, creating two images offset by exactly 3.06 mm. The clinician looks through the applanation head and adjusts the pressure until the half circles just overlap one another (*Fig. 2.5.15*). At this point, the circle is exactly 3.06 mm in diameter, and the reading on the

## GOLDMANN APPLANATION TONOMETER

**Fig. 2.5.12** Photograph of a Goldmann applanation tonometer in working position on a slit-lamp microscope.

tonometer (multiplied by a factor of 10) represents the intraocular pressure in millimeters of mercury (*Fig. 2.5.16*).

## Specular Microscope

A number of significant obstacles stand in the way of easy microscopical observation of the living corneal endothelium. First, the reflection from the front corneal surface interferes with a sharp view of the endothelium. Second, the intervening stromal layers backscatter light, which decreases the contrast of the endothelial details. In addition, when the stroma becomes thick and edematous, the views of the endothelium become hazy. Finally, because of the small difference in index of refraction between the cornea (1.376) and the aqueous (1.336), only 0.02% of the incident light (for most angles of incidence) is reflected from the interface between corneal endothelium and aqueous.<sup>10</sup>

To eliminate the bothersome reflection from the front corneal surface, two approaches are used. An increase in the angle of incidence moves the anterior reflection to the side so it covers less of the specular reflection from the endothelium. This approach alone is used in the noncontact technique. If the cornea could be thickened artificially (without an increase in light scatter), this would move the surface reflection further to the side. With use of a contact lens that has a coupling fluid of index of refraction similar to that of the cornea, the surface reflection is eliminated and the corneal thickness may be assumed to include the contact lens thickness also. The reflection from the surface of the contact lens replaces that of the corneal surface. However, because of the thickness of the contact lens, the surface reflection is moved well over to the side (*Fig. 2.5.17*).

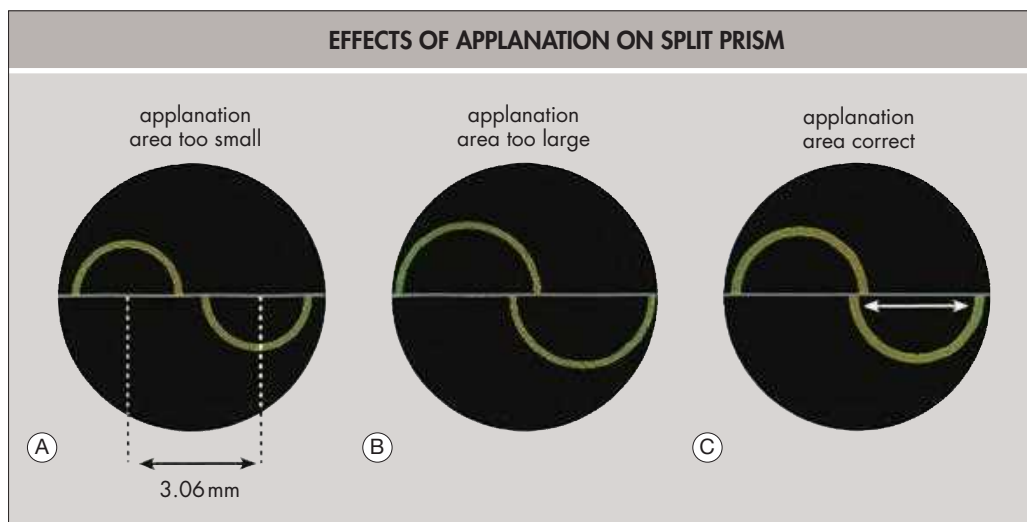

The magnification needed to yield important details about the shape and size of the endothelial cells lies between a magnification of  $\times 80$  and  $\times 250$ . Of course, a lower magnification photograph may allow an accurate count of the endothelium. In normal individuals the number of endothelial

**Fig. 2.5.13 Effect of Force on Cornea.** (A) When a flat surface is applied to the cornea with enough force ( $w$ ) to produce a circular area of flattening greater than 3.06 mm in diameter, the force caused by scleral rigidity ( $r$ ) is greater than that caused by the tear film surface tension ( $s$ ). (B) When the force of the flat surface produces a circular area of flattening exactly 3.06 mm in diameter, the confounding forces caused by scleral rigidity and tear film surface tension cancel each other. The applied force ( $w$ ) then becomes directly proportional to the intraocular pressure ( $p$ ).

**Fig. 2.5.14 Fluorescein-Stained Tear Film.** When viewed through a transparent applanation head, the fluorescein-stained tear film appears as a circular ring (A). Greater applanation pressure causes the ring to increase in diameter (B).

**Fig. 2.5.15 Effects of Applanation on Split Prism.** The split prism in the applanation head creates two images offset by 3.06 mm, allowing greater ease in determining when the circular ring is exactly 3.06 mm in diameter. When the area of applanation is smaller than 3.06 mm, the arms of the semicircles do not reach each other (A). When the area of applanation is greater than 3.06 mm, the arms of the semicircles reach past each other (B). When the area of applanation is exactly 3.06 mm, the arms of the semicircles touch each other (C). This is the endpoint at which the intraocular pressure can be measured.

**Fig. 2.5.16 Low Applanation Pressure.** When the applanation pressure is too low (1.0 dyne in this illustration) the circular ring is smaller than 3.06 mm in diameter, and the arms of the ring do not reach each other in the split image (A). When the applanation pressure is too high (3.0 dynes in the illustration) the circular ring is larger than 3.06 mm in diameter, and the arms of the ring stretch past each other in the split image (B). When the applanation pressure creates a circular ring exactly 3.06 mm in diameter, the arms of the ring just reach each other in the split image (C). In this illustration, the endpoint is reached at 2.0 dynes of applanation pressure, which corresponds to an intraocular pressure of 20 mm Hg.

cells per square millimeter decreases with age, while the size of the cells increases with age.

## OPERATING MICROSCOPE

The operating microscope (Fig. 2.5.18) works on principles similar to those of the slit-lamp microscope. Both have the following optical components:

**Fig. 2.5.17 Optics of Endothelial Specular Microscopy Using a Contact Lens.** (Adapted from Bigar F. Specular microscopy of the corneal endothelium. In: Straub W, editor. Developments in ophthalmology, vol. 6. Basel, Switzerland: Karger; 1982. p. 1–88.)

**Fig. 2.5.18 External Photograph of an Operating Microscope.**

(1) astronomical telescope, (2) inverting prism, (3) Galilean telescope, (4) objective lens, (5) light source, and (6) binocular viewing system (Fig. 2.5.19). Unlike the slit-lamp microscope, the operating microscope's illumination source is not slit-shaped, and the working distance for the operating microscope (the distance from the objective lens to the patient's eye) is longer to accommodate the specific requirements of ocular surgery.

The working distance of this microscope is equal to the focal length of the objective lens. Commonly used objective focal lengths in ophthalmic surgery are 150 mm, 175 mm, and 200 mm. Use of the proper working distance can greatly lessen back and neck strain on the surgeon, especially during lengthy operations. A difference of 25 mm often can affect body comfort and the positioning of the surgeon's arms and hands.

The total magnification of the operating microscope is equal to the product of the magnifications of its various components. Because several different lenses are available for the objective and the eyepiece, magnification can be controlled. Smoothly variable magnification changers (zoom Galilean telescopes) are now incorporated into many operating microscopes. The  $\times 12.5$  eyepiece is the most popular choice for ophthalmic surgery, with magnification from  $\times 6$  to  $\times 40$ .

Various illumination systems are available, but the most important system for ophthalmic surgery is known as *coaxial illumination*. This

**Fig. 2.5.19 Schematic Diagram of an Operating Microscope.** The major components include: the eyepiece, an astronomical telescope system, which provides most of the magnification (a); an inverting prism, such as a Porro–Abbe prism, to correct for the inverted image produced by the eyepiece (b); a magnification changer, such as a Galilean telescope system, in which different lenses can be introduced in order to change the degree of magnification (c); and the objective lens, which adjusts the working distance (d). Two parallel optical systems, each a mirror image of the other, provide a stereoptic view of the patient's eye.

system is especially useful for visualization of the posterior capsule and for vitreous surgery. Fiberoptic delivery systems reduce heat near the microscope and facilitate the changing of bulbs during surgery.

## KERATOMETER AND CORNEAL TOPOGRAPHER

In the early 1600s Christopher Scheiner sat a person opposite a window. The subject's anterior corneal surface with its overlying tear film acted as a convex mirror and produced a small image of the window. Today we refer to that image as the first Purkinje image or simply the mire or mires. Scheiner compared the corneal mire to similar images produced by glass spheres of differing sizes and concluded the cornea had about the same shape as the sphere that produced the image most closely matching the mire.

The technique has been greatly refined. Today the mires are measured by an electronic camera, but the same basic principle introduced four centuries ago remains fundamentally unchanged. An object of known dimensions is placed in front of the cornea, which like any convex mirror produces a virtual erect image of the object. The dimensions of the mires are measured, and from this information an attempt is made to infer corneal shape and optical properties.

The basic problem, however, is that there is no definite relationship between the dimensions of the mires and the shape of the cornea.<sup>11</sup> Put another way, there are infinitely many corneas that can produce identical mires. Consequently, it is impossible to derive the shape of the cornea

from the shape of the mires. Implicit in all corneal measuring instruments based on Scheiner's method are two assumptions: (1) that the cornea is restricted to a specific geometrical class, and (2) that the instrument is aligned on the corneal axis. In many cases, at least one of the assumptions (and often both) is invalid.

Consider the simple case of a rotationally symmetrical cornea that can be described by two parameters: vertex curvature and eccentricity. Vertex curvature is directly proportional to power, and eccentricity describes how quickly the cornea flattens to influence aberrations. The two variables are independent, e.g., a 45.00 D hyperboloid can have many different eccentricities, and a hyperboloid of a given eccentricity can have many different powers. Thus to describe the shape and optical properties of a hyperboloid it is necessary to measure both eccentricity and power, but ophthalmometers such as the Bausch & Lomb keratometer or Javal–Schiotz measure neither.

Instead ophthalmometers assume the cornea is spherical. Under the spherical constraint the only remaining question is what is the radius of the sphere? The keratometer gives the radius of the sphere that produces the same mires as those produced by a hyperboloidal cornea. Two corneas with the same power but different eccentricities will produce different K-readings. Likewise, corneas of different power may produce the same K-readings.

It is important to realize that the keratometer was not intended to measure corneal shape or optical properties. The device was introduced shortly after World War II and was originally designed to assist in fitting rigid contact lenses that had spherical posterior surfaces, so the assumption of a spherical cornea was reasonable for the intended purpose. Originally, contact lens base curves had to be specified as a radius (in millimeters), so the keratometer was calibrated in millimeters. Some clinicians preferred to specify base curves in diopters, so later instruments were calibrated in diopters using the conversion formula:

$$\text{Diopters} = \frac{337.5}{\text{Radius (mm)}}$$

This conversion formula is not optically correct because it assumes the corneal refractive index is 1.3375, not the correct value of 1.376. The conversion underestimates the power of the anterior cornea and tear film. However, because the posterior corneal surface has negative power, this formula is a better estimate of overall corneal power. This was of no consequence at the time, because the only purpose of this formula was to allow laboratories to convert base curves specified in diopters into millimeters for purposes of fabrication. This formula had the advantage of making a radius of 7.5 mm exactly equal to 45 D. Today, ophthalmometers are available that give K-readings in millimeters, diopters, or both.

With the general acceptance of intraocular lenses (IOLs) in the mid-1970s, ophthalmometers gained a new clinical role for which they are not ideally suited—the estimate of corneal power to calculate implant power. Theoretical formulas incorporated K-readings as if they were actually accurate measurements of corneal power. It is fair to say that most of the clinical community did not fully appreciate the distinction between K-readings and corneal power. According to theory, if corneal power changes by 1.00 D, implant power should change by more than one diopter. It came as a complete surprise when the SRK equation—the first formula based on statistics rather than theory—suggested that a 1.00 D change in K-readings should change the implant power by only 0.9 D. This result proves that K-readings are not a measurement of corneal power.

Nevertheless, the SRK equation proved that corneal power and K-readings are correlated. The spherical aberration of a hyperboloidal cornea can be eliminated with the right eccentricity. Indeed, the eccentricity of most human corneas varies over a narrow range that is quite close to the optimal (spherical aberration free) value. Because corneal eccentricity normally varies over a limited range, K-readings correlate with—but are not measurements of—corneal power.

The success of the SRK formula should have alerted the clinical community to the limitations of the Scheiner approach, but it did not. With the advent of refractive surgery, ophthalmometers were again used to correlate changes in refractive error to K-readings. Again, it was soon found that K-readings did not correlate with changes in refractive error. The reason for the poor correlation is that keratorefractive surgical procedures change corneal eccentricity, destroying the statistical relationship that normally exists between power and eccentricity. The result is that K-readings no longer reflect corneal power in a predictable way.

Refractive surgeons quickly recognized the shortcomings of ophthalmometers but did not understand the underlying reason. Many believed

that the single circular mire interrogated only a small region of the cornea and additional rings would overcome the problem, but they do not. The fundamental problem, as stated before, is that no definite relationship exists between the mires and corneal shape, even when multiple rings are used.

Alignment is another critical factor affecting the “accuracy” of corneal topography systems. Most algorithms assume the instrument’s optical axis coincides with the corneal axis, but it does not. The early corneal topography instruments lacked any alignment method, which led to unreproducible results. Repeated measurements on the same patient were often wildly different, which obviously cast serious doubt on the reliability of these devices. Later instruments used the pupil, not the corneal vertex, for alignment. A consistent alignment procedure produced reproducible but not necessarily accurate measurements. Inappropriate alignment even in today’s instruments can produce artifacts that have been mistakenly attributed to early keratoconus.<sup>12</sup>

Despite their failings, most corneal measurement systems in clinical use are based on the Scheiner principle. Clinicians should use these systems with an appreciation for their limitations. Fundamentally, no relationship exists between the mires and corneal shape, because infinitely many different corneas can produce identical mires. However, the cornea is not infinitely variable, so correlations occur between the mires and the cornea that make it possible to use ophthalmometers and video keratometry to calculate IOL power and assist in other clinical evaluations. Clinicians should be aware, however, that the more irregular or misaligned the corneal and instrument axes, the more likely that the data are unreliable.

## LENSMETER

For most of the twentieth century, the lensmeter (also known as the lensometer or vertex meter) changed very little. However, in the 1970s a number of automatic lens analyzers appeared that eliminated almost all human involvement and quickened the determination of new prescriptions.

In this chapter, the basic principles of the traditional lensmeter are reviewed to outline its strengths and weaknesses and thus help to appreciate the usefulness of the automatic devices.

The lensmeter does not measure the focal length of the unknown lens. It measures the vertex power, which is the reciprocal of the distance between the back surface of the lens and its secondary focal point; this distance is known as the *back focal length*.

A simple lensmeter (Fig. 2.5.20) is an optical bench that consists of an illuminated, movable target, a powerful fixed-field lens, and a telescope eyepiece focused to infinity.<sup>13</sup> The key element is the field lens; without this, to measure the merest 0.25 D lens would require a lensometer of the optical bench type to be over 4 m long. The fixed-field lens is situated so that its focal point is on the back surface of the unknown lens being analyzed, which, in turn, sends parallel light to the observation telescope. Thus the small movement of the target is amplified optically and in such a way that the distance between the target and field lens always is directly

proportional to the power of the unknown lens (an example of Badal’s principle). Such an arrangement allows the instrument’s linear scale to be read in diopters.

To determine the power of each principal meridian of an unknown lens, the lens simply is inserted into the lensmeter, the principal meridian located, the target lines focused sharply, and the power recorded. The second target, set 90° from the first, is refocused and the new power recorded. Once the powers in the two principal meridians and the axes are known, the final prescription is calculated.

The automatic device rapidly measures the powers in all meridians, selects the meridians with the greatest difference in power between them, and designates these as the major meridians of the lens. The device is programmed to calculate the prescription and print out the result. The entire procedure takes less than 1 minute from spectacle insertion to printout.

The main advantage of the automated lensmeter is its elimination of human error. In today’s busy ophthalmic office, in which technicians and doctors juggle many mental tasks at the same time, a clear advantage exists to a device that does not need to be focused, have numbers written down, or require calculations to be made.

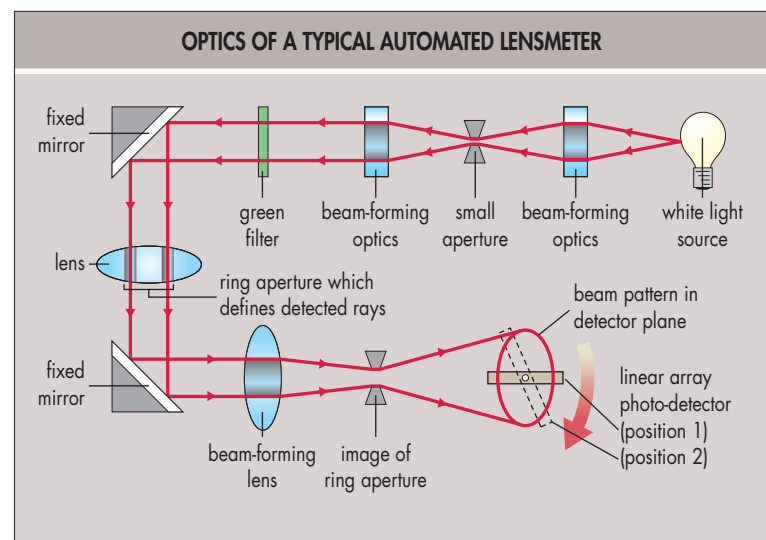

If an automated lensmeter does not focus a sharp image, how does it work? It simply measures the deflection of a fixed number of light rays produced by the unknown lens. To do this, the direction of the rays must be known before they enter the lens. The easiest way to accomplish this is to have them all enter parallel to one another. Fig. 2.5.21 shows a beam of collimated green light (which eliminates chromatic aberration) incident to the unknown lens. Thus a circle of light of a known dimension strikes the lens. The refracted light is passed through a ring aperture to tailor the size of the new beam to the size of the board of light detectors. By deflection of the parallel beam in its unique manner, the unknown lens produces a new pattern (i.e., a smaller or larger circle or an ellipse), which is detected and carefully measured by an array of photodiodes. These measurements yield deflection information that is fed into a small computer that calculates the lens parameters (powers, axis, adds, prisms), and a printer creates a record of the parameters. Because these devices measure ray deflections, if the lenses in the lensmeter are tipped at all, the deflection is altered and erroneous results are produced.

Another small error arises in the measurement of the add of a bifocal. All automated lensmeters are designed to measure the vergence of the light that exits a lens when parallel light enters it. However, light that enters the add when worn by a patient is typically divergent (i.e., originates at 16 inches [40 cm] or the reading distance from the spectacle plane). The error is significant only in high-powered lenses, such as for an aphakic correction. To minimize this error, the distance and near powers are measured using the back surface of the lens (in the position usually occupied by the front surface).

Accurate measurement of the progressive multifocal lens presents a problem with many lensmeters. The operator must first align the lens to measure the distance correction, bind then find and realign, and measure the area of the lens with the maximum add.

**Fig. 2.5.20 The Lensometer Resembles an Optical Bench.** The movable illuminated target sends light to the field lens, with the target in the endpoint position. Because the focal point of the field lens coincides with the position of the unknown lens, all final images are the same size (Badal principle).

**Fig. 2.5.21 Optics of a Typical Automated Lensmeter.** Parallel light strikes the unknown lens. The refracted light rays (which are confined to a pencil beam within an annulus) ultimately strike an array of electronic photoreceptors.

## AUTOMATED REFRACTOR

Any clinician who has asked enough patients “Is it better with lens 1 or lens 2?” must have dreamed of an automated refractor.<sup>14</sup> After all, the eye is a partial optical bench. The fundus can be a serviceable target if illuminated. The cornea and lens make a passable aspherical focusing system. To complete the optical bench, a positive lens needs to be placed before the eye to form a real aerial image of the fundus, as in indirect ophthalmoscopy. Except that distances are not standardized and calibration is not present, an indirect ophthalmoscope has most of the essential elements of an objective refractor.

Modern instruments have two sources of light. First, the target is illuminated with visible light for fixation and accommodation control and, second, a low-intensity infrared or near-infrared source sends light into the patient’s eye, which is “seen” by a sensor. The optometer must use “invisible” (or at least dim, unobtrusive) light for measurement to preclude an unwanted stimulus to accommodation and to allow comfortable fixation. These two (visible and infrared) systems usually are derived from a single incandescent lamp by the use of filters. For example, a cut-off filter of 800 nm allows only infrared light to enter the system.

The area of retina irradiated by infrared radiation produces a real image within the optometer. This image is analyzed by photoelectric means using an infrared-sensitive device. The use of infrared for focus evaluation presents a few problems. For example, an examiner cannot calibrate the focusing system “by eye” but must use an indirect method. In terms of accuracy, the eye’s chromatic aberration is a problem. Anyone familiar with the duochrome (red–green) test knows that the human eye focuses light of various wavelengths differently. Because the goal is to learn the eye’s refractive error in visible (yellow) light, a correction factor of about 1.00 D must be built into any infrared device.

It is valuable to consider some problems that had to be solved in the design of modern objective refractors: accommodation, subjective alignment, and focusing.

**Accommodation.** Accommodation associated with the use of a target that is optically distant but objectively near may induce errors in the measurement of refraction. Modern devices use a fogging lens through which the fixation target is viewed. The subject hopefully learns that accommodation tends to make the visible target even more blurred and thus relaxes accommodation. Occasional failure of accommodation to relax under a fog is presumed to occur because of an awareness that the target is not truly distant. This phenomenon has been termed *instrument myopia*.

**Subjective alignment.** It is almost paradoxical to request a subject to simultaneously look at a fixation target and not attempt to clear it by accommodation. These divergent responses are required, however, if refraction is to be measured accurately for foveal vision. Accordingly, when the examiner aligns the optometer with respect to the subject’s pupil as the subject fixates the target, proper overall alignment must be ensured. At the same time, a fogging lens provides a disincentive to accommodate.

**Focusing.** Modern objective refractors are focused automatically, which eliminates the variability otherwise introduced by examiner accommodation. Automatic focusing for various meridians is accomplished swiftly, with the number and locations of meridians actually scanned depending on the method of image evaluation and on the approach to refractive error analysis used in the particular instrument. The computational power of the microprocessors found in today’s automated refractors allows refraction to be calculated within 10 seconds or less. This high speed tends to negate one of the major problems associated with older manual devices, such as momentary changes in fixation or accommodation or both that may take place during the course of measurement.

Most objective optometers use one of three methods for focus analysis: the retinoscopic principle, Scheiner’s disc principle, or the grating focus principle.

**Retinoscopic principle.** Bausch and Lomb’s Ophthalmometron was the first clinical automated refractor to utilize the retinoscopic principle.<sup>15</sup> No longer commercially available, this instrument used paired light sensors to register movement of the retinoscopic reflex. For example, if sensor 1 was stimulated before sensor 2, an analog of a retinoscopic “with” existed. Conditions that gave rise to a retinoscopic “against” caused sensor 2 to be stimulated first. In any event, a servomechanism found the focus in one meridian and attempted to maintain focus as each meridian was scanned in turn. The Ophthalmometron produced a graph that displayed the refraction in each meridian. Modern automated refractors are much more rapid and display refractive data directly in numeric form.

**Scheiner’s disc principle.** In the early seventeenth century, Fr. Christopher Scheiner observed that an in-focus candle is seen singly, whereas an out-

**Fig. 2.5.22**  
**Principle of Scheiner’s Disc.** Light enters the two pinholes and produces two images on the retina until the light is brought to a focus. (Adapted from Guyton DL. Automated clinical refraction. In: Duane T, editor. Clinical refraction, vol. 1. Baltimore, MD: Harper & Row; 1987. p. 1–43.)

of-focus candle is seen double when viewed through paired apertures separated by a distance slightly less than the diameter of the pupil. An automatic focusing device that uses Scheiner’s disc principle divides the rays that emerge from a subject’s eye into two bundles and then seeks the point at which these intersect. For example, a photoelectric sensing device might register an endpoint for a particular meridian under the condition that all the light falls on one sensing element rather than two. The 6600 Autorefractor<sup>16</sup> is an example of an instrument that operates on Scheiner’s principle (Fig. 2.5.22).

**Grating-focus principle.** In the grating-focus method, an image of a luminous target grating is formed on the retina. The sharpness of the aerial image of the illuminated “retina grating” is assessed continuously, usually by a scanning process. A high-speed servomechanism varies the focusing lenses until the actual grating image is as sharp as a standard in-focus image provided by the device.

## MAGNIFYING DEVICES

### Angular Magnification

In addition to transverse and axial magnification, angular magnification is another parameter used to characterize the performance of optical instruments. All focal optical systems (i.e., those with first order properties described by three pairs of points—focal, principal, and nodal) have an angular magnification of 1. Afocal systems such as telescopes that do not have focal, nodal, or principal points can have angular magnifications that differ from 1.

### Magnifying Glass

The simplest way to make an object appear larger is to move it closer to the eye, increasing the angular subtense of the retinal image (measured with respect to the eye’s posterior nodal point). The fundamental limitation to this approach is the eye’s near point, determined by accommodation. With placement of a single positive ancillary lens between the object and eye, the angular subtense can be increased beyond what can be achieved by accommodation alone. How much magnification is produced by a lens of a given power? The answer depends on where the object is placed relative to the ancillary lens.

The following analysis is based on paraxial optics, which is to say that all angles are small and aberrations are not involved. If the patient has  $A$  diopters of accommodation then in the unaided eye the object of height  $h$  at the near point subtends an angle of

$$\alpha = h(A).$$

If an auxiliary positive thin lens of power  $P$  (the magnifier) is placed in front of the eye such that the object is in the magnifier's front focal plane the angular subtense of the retinal image becomes

$$\alpha' = h(P).$$

The ratio  $(\alpha'/\alpha)$  compares the angular subtense of the retinal image when a magnifier is used divided by the image subtense without a magnifying lens and is the angular magnification.

$$Ma = \alpha'/\alpha = (P/A)$$

By convention, it is often assumed that the patient has 4 diopters of residual accommodation, so the formula becomes

$$Ma = (P/4)$$

The last equation is the standard formula often quoted in textbooks, but since accommodation varies from patient to patient, the last equation does not reflect the correct value in many cases. By preserving the patient's accommodation as a variable, the equation  $Ma = P/A$  more accurately reflects the magnification produced by a simple magnifier for a specific patient.

When the object is placed in the front focal plane of the auxiliary lens, however, the patient's accommodation is completely relaxed, which wastes some power that could be used for further magnification. The maximum amount of angular magnification is achieved when the ancillary lens produces a virtual image at the near point of accommodation. In which case the angular magnification becomes

$$Ma = 1 + P/A$$

or using the conventional value for  $A = 4.00$  D

$$Ma = 1 + P/4$$

which is another formula often cited in textbooks. Again, a more versatile equation is obtained by preserving the patient's accommodation as a variable. In any case, the lower the patient's accommodation, the greater the benefit of the simple magnifier.

## Galilean Telescope

To calculate the magnification of a telescope, the angle of incident parallel light is compared with the angle of the parallel rays of emergent light. From Fig. 2.5.23, the entrance angle is given by  $y_1/f_o$  (where  $f_o$  is the focal length of the objective lens), the emergent angle is given by  $y_1/f_e$  (where  $f_e$  is the focal length of the eyepiece lens), and the magnification is given by Eq. 2.5.1.

$$\frac{y_1/-f_e}{y_1/f_o} = \frac{-f_e}{f_o} \quad \text{Equation 2.5.1}$$

For example, if a Galilean telescope has an angular magnification of  $\times 3$  and the eyepiece is  $-12$  D, the power of the objective is given by Eq. 2.5.2.

$$3 = \frac{12}{f_o} \quad \text{Equation 2.5.2}$$

$$f_o = 4 \text{ D}$$

As another example, for a telescope of magnification  $\times 3$  and tube length ( $L$ ), the distance between objective and eyepiece, of 22 cm,  $f_o$ , and  $f_e$  are given by Eq. 2.5.3.

$$\begin{aligned} -3 &= \frac{f_o}{-f_e} \\ -3f_e &= f_o \\ L &= f_o - f_e \\ 22 &= -3f_e - (-f_e) \\ 22 &= -2f_e \\ -f_e &= -11 \text{ cm} \\ f_o &= 3.3 \text{ cm} \end{aligned} \quad \text{Equation 2.5.3}$$

**Fig. 2.5.23 A Galilean Telescope.** Note the objective lens takes parallel light and places a real image at the focal point of the negative eyepiece. The eyepiece takes the incident convergent light and renders rays parallel.

**Fig. 2.5.24 A Simple Microscope.** A positive lens (working distance lens) is placed in front of a Galilean telescope. This lens takes light from an object located at its focal point and renders the rays parallel for the Galilean telescope part of the device.

## Simple Microscope (Operating Loupe)

The principles of this device are similar to those of a Galilean telescope, even though it works only if it receives parallel light and a microscope is used to look at close objects.

However, if a magnifying lens ( $f_w$ ) is added, the focal length of which is the working distance, then the magnifying lens introduces parallel light to the telescope, as shown in Fig. 2.5.24, and the total magnification is given by Eq. 2.5.4.

$$\frac{f_w}{4} \times \frac{f_e}{f_o} \quad \text{Equation 2.5.4}$$

For example, for a loupe with a  $\times 3$  telescope and a  $+8$ D working lens (reading cap) the magnification =  $(8/4) \cdot 3 = \times 6$ .

# Wavefront Optics and Aberrations of the Eye

Edmond H. Thall

# 2.6

**Definition:** An aberration is any deviation of the path of a ray of light from geometrically ideal behavior.

## Key Features

- Aberration theory is strictly confined to geometrical optics and ignores any aspects of physical optics such as diffraction and interference.
- Originally, wave aberrations were applied only to symmetrical optical systems, and each aberration was represented by a unique polynomial.
- Today other expansions, particularly the Zernike polynomials, are most commonly used, and usually each polynomial is a combination of pure aberrations.
- In any case, after defocus and regular astigmatism, the most important aberrations are coma and spherical aberration.

## INTRODUCTION

From a clinical perspective, aberration theory is simply an extended treatment of refractive error. Only hyperopia, myopia, and regular astigmatism are correctable by spectacles,<sup>1</sup> so in the past these were the only aberrations of clinical interest. The existence of other refractive errors was certainly recognized,<sup>2</sup> but because they were not correctable, clinicians had no need to study them in depth. Instead, the many aberrations not correctable by spectacles were relegated to a single broad category—irregular astigmatism. It is probably fair to say that even today many clinicians believe irregular astigmatism exists only in pathological cases and is not present in normal eyes.

For centuries, designers of optical instruments (e.g., telescopes, microscopes) had methods of correcting aberrations that could not be implemented clinically. Consequently, engineers have carefully characterized the individual aberrations that clinicians refer to collectively as irregular astigmatism.<sup>3</sup> With the advent of keratorefractive surgery came the intriguing possibility of correcting at least some refractive errors not correctable by spectacles. Keratorefractive surgery also brought the disconcerting complication of increased irregular astigmatism in some cases.<sup>4</sup> For the first time it was necessary for clinicians to explore irregular astigmatism more thoroughly. Fortunately, rather than reinvent the wheel, ophthalmologists can turn to the already well-developed aberration theory used by lens designers.

## RAY ABERRATIONS

Aberrations can be described by two different but closely related methods: ray and wave aberrations. When a ray is precisely traced through an optical system using the laws of geometrical optics (e.g., Snell's law) it is found that usually the ray does not exactly intersect the ideal image point. The displacement of the actual ray from the image point is the ray aberration. When a pencil of rays (by definition all originating from a single object point) are traced, the result is a spot diagram (Fig. 2.6.1).

For a specific and familiar example, consider the spot diagram for the axial object point at infinity of a theoretical eye with a 4 mm pupil and  $-1.00$  D of myopia and no other aberrations. A spot diagram can be calculated anywhere within an optical system, and typically several are calculated in the vicinity of the theoretical image plane. The set of through-focus spot

diagrams show that a stigmatic focus occurs about one-third of a millimeter anterior to the retina. The size of the spot diagram increases as the pupil enlarges, but the location of the stigmatic focus (and, therefore, the power of the corrective spectacle lens) does not change with pupil size, so the aberration is said to be pupil independent. Likewise, regular astigmatism is also pupil independent, which is why it is unnecessary to check pupil size to prescribe spectacles. The aberration known to lens designers as defocus encompasses both myopia and hyperopia.

In 1857 Ludwig von Seidel described five basic monochromatic ray aberrations of rotationally symmetrical optical systems.<sup>5</sup> When studied individually, each aberration can be easily identified by its characteristic spot diagram. However, virtually all optical systems have many different aberrations. The spot diagrams of actual optical systems are a complex combination of several aberrations. It is difficult to identify and quantify the many individual aberrations from spot diagrams of actual optical systems.

In the early 1950s HH Hopkins developed a different, wavefront-based approach that simplified the definition, identification, and quantification of aberrations.<sup>6</sup> The two approaches, ray and wavefront, are not mutually exclusive but rather complementary.

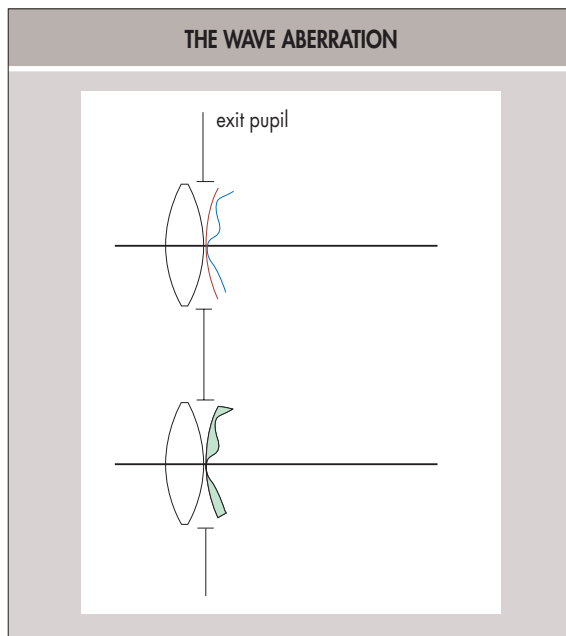

## THE WAVEFRONT APPROACH TO ABERRATIONS

Aberration theory falls within the discipline of geometrical optics,<sup>7</sup> so diffraction and other wave phenomena are completely ignored. In aberration theory, light propagation obeys the basic laws of reflection, refraction, and rectilinear propagation. All three laws are encompassed by Fermat's principle, which states that between any two points light travels the fastest path.

Ideally, a pencil of rays filling the entrance pupil of an optical system emerges from the exit pupil as a pencil converging to a perfect image point,<sup>8</sup> i.e., a stigmatic focus. The reference sphere is an imaginary spherical surface centered on the ideal (paraxial) image point and intersecting

**Fig. 2.6.1 Ray Aberration and Spot Diagrams.** In principle, the image ray should intersect the ideal image point but usually does not. The separation between any ray and the ideal image point is the ray aberration (for that particular ray). A spot diagram shows the intersection of multiple rays (from a single object point) in any plane perpendicular to the axis. Through-focus spot diagrams are a set of spot diagrams in the vicinity of the ideal image point showing the position of the best focus. In this case (but not usually), the best focus is stigmatic but in front of the ideal image point.

**Fig. 2.6.2 Definition of Wave Aberration.** The reference sphere is centered on the desired image point and intersects the center of the exit pupil (shown top, in red). An ideal optical system would produce an actual wavefront that coincides with the reference sphere. A real optical system produces a wavefront that does not coincide with the reference sphere (shown top, in blue). The difference between the actual wavefront and the reference sphere is the wave aberration (shown bottom, in green).

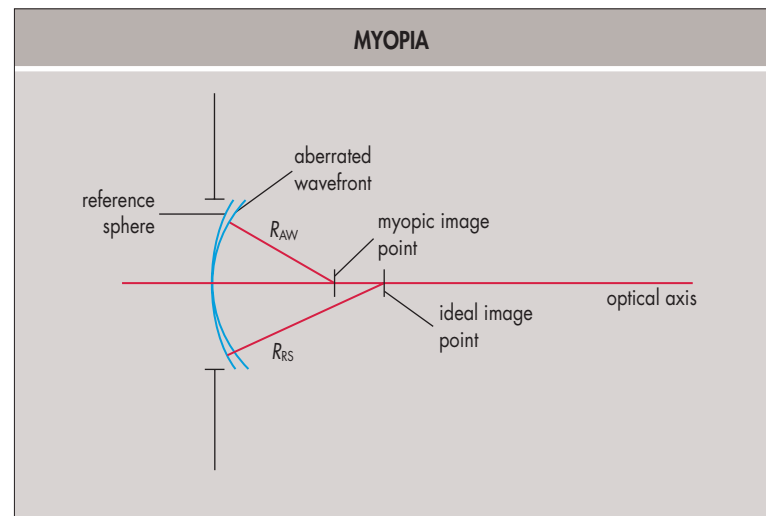

the center of the exit pupil.<sup>9</sup> According to Fermat's principle, to achieve a stigmatic focus, all light radiating from the object point at a particular instant must arrive simultaneously at the image point, or equivalently, must cross the reference sphere simultaneously.

In most cases, image rays do not emerge from the exit pupil as a pencil converging to a single point but rather converge to a small irregularly shaped region.<sup>10</sup> In other words, the focus is not stigmatic. It always is possible to draw a surface through the center of the exit pupil that all rays cross simultaneously, and when the focus is not stigmatic, that surface—called the actual wavefront—is not spherical. The difference between the reference sphere and actual wavefront is the wave aberration (Fig. 2.6.2).<sup>11</sup> The wavefront and reference sphere are both surfaces, and the difference between these two surfaces, the wave aberration, is likewise a surface. To give an analogy, consider the Earth's surface as the actual wavefront and sea level as the reference sphere. Height above (or below) sea level is analogous to the wave aberration.

The word wavefront is perhaps an unfortunate choice, suggesting that it is somehow related to the wave nature of light. However, as noted, aberration theory is based on geometrical optics that by definition ignores the wave properties of light. A pencil of object rays entering the optical system upon emerging from the exit pupil always “reaches” the wavefront simultaneously, so the wavefront is a surface of equal time. Arguably, the term isochrone (equal time) is more descriptive, but wavefront is too entrenched to change.

It is a common misconception that there is only one set of aberrations for each optical system. In fact, there is a different set of aberrations for every object point. This discussion began with a single pencil of object rays by definition from a single object point. Each object point produces its own pencil, and each object pencil has its own unique set of aberrations, although nearby object points have very similar aberrations.

Stigmatic focus means image rays converge to a *perfect* point either at the ideal image point or elsewhere.<sup>12</sup> Because of diffraction, the focus can never be stigmatic, but geometrical optics ignores diffraction. Using only refraction, reflection, and rectilinear propagation, focus can, in theory, be stigmatic. Some use the term “astigmatism” to refer to any focus that is not stigmatic, but the word astigmatism also has several other more specific meanings. To avoid confusion in this chapter, “nonstigmatic” refers to any focus that is not stigmatic. The term astigmatism is reserved for regular astigmatism or astigmatism of oblique incidence. When the focus is nonstigmatic, rays do not converge to a perfect point even at the best possible focus. As in defocus, aberrations can still exist even when the image is stigmatic. If rays converge to a perfect point but the image point is not at the position predicted by the vergence equation, then an aberration is present.

**Fig. 2.6.3 Myopia.** In myopia, the aberrated wavefront is spherical but has a shorter radius ( $R_{AW}$ ) than the reference sphere ( $R_{RS}$ ).

Returning to the example of a theoretical eye with  $-1.00$  D of myopia, the reference sphere is centered on the ideal image point. As shown earlier, in myopia, the image is stigmatic but anterior to the ideal image point. The wavefront emerging from the exit pupil therefore also is spherical but centered on a point anterior (i.e., to the left) of the ideal image point. The difference between the actual wavefront and reference sphere is the wave aberration surface (Fig. 2.6.3). It is worth noting that the maximum separation between the reference sphere and the wavefront is a mere  $1.5 \mu\text{m}$ , which is at the edge of the pupil. For midperipheral and central rays the wave aberration is less.

When wave aberrations are displayed on a graph, the optical axis is rotated  $90^\circ$  from horizontal to vertical. The wave aberration produced by myopia has a bowl shape.<sup>13</sup> All myopias, whether large or small, have the same characteristic bowl shape. The amount of myopia changes the bowl's depth and steepness of its edges but does not change its basic bowl shape. The wave aberration for hyperopia also is bowl shaped but the bowl is inverted (i.e., spills water). As both refractive errors have the same fundamental shape, lens designers classify them as the single aberration, defocus just as clinicians use “sphere” to specify either myopic or hyperopic correction when writing prescriptions. However, positive defocus is myopia and negative defocus is hyperopia, which may be counterintuitive to clinicians. The difference arises because lens designers classify defocus by the shape of the wave aberration, whereas clinicians think in terms of the power of the correcting lens.

## SPHERICAL ABERRATION

In spherical aberration (SA), rays near the center of the lens focus at or close to the ideal image point, whereas more peripheral rays focus in a different location. In positive SA, peripheral rays focus in front of the ideal image point, and the more peripheral the ray the more anterior its focus (Fig. 2.6.4). In negative SA, peripheral rays focus behind the ideal image point and, again, the more peripheral the rays, the more posterior their focus. The wave aberration representing SA also has a bowl shape.<sup>14</sup> In fact, SA looks more like a bowl than does defocus. Compared with defocus, the wave aberration of SA has a flatter broader center and the edges become much steeper than the bowl representing defocus.

When SA is present, the location of the best focus is no longer at the ideal image point predicted by the vergence equation ( $U + P = V$ ). Positive SA shifts the best focus toward myopia, whereas negative SA shifts the focus toward hyperopia. However, even at the best position the focus is not stigmatic.

SA is strongly pupil dependent, because the position of best focus changes with pupil size. In positive SA, myopia increases as the pupil enlarges, which explains the uncommon clinical condition known as night myopia. In patients with a large amount of positive SA the increase in myopia under low light conditions is typically about  $-0.50$  D and produces symptoms of blurred vision and halos. The condition can be treated by a second pair of spectacles or clip-ons with an extra  $-0.50$  D over the daytime correction for night use.

SA can be reduced by aspherical refracting surfaces that flatten peripherally, which is typical of most corneas. Indeed, the cornea can flatten so

**Fig. 2.6.4 Positive Spherical Aberration.** Central rays (red) focus at the paraxial (ideal) image point but peripheral rays focus anteriorly. The more peripheral the ray, the more anterior its focus. In negative spherical aberration peripheral rays focus posterior to the ideal image point. Notice that spherical aberration shifts the position of the best focus.

**Fig. 2.6.5 Coma.** When rays are incident on a lens at an angle the focus flares out in a pattern suggestive of a comet's tail.

much that it overcompensates, producing negative SA. Theoretically, large amounts of negative SA would cause a hyperopic shift in low light conditions, but this is rarely if ever seen clinically. The Stiles–Crawford effect<sup>15</sup> (see later) also reduces the effect of SA on vision. The fact that refractive error usually does not fluctuate with pupil size in most eyes suggests that SA is adequately compensated over the typical range of pupil sizes.

It has been claimed that the crystalline lens compensates for corneal SA, and when the crystalline lens is removed, it should be replaced by an SA-compensating implant. However, studies that have measured SA in the cornea and crystalline lens separately have not found any tendency for the crystalline lens to compensate for corneal SA.<sup>16</sup> Also, corneal SA varies from person to person,<sup>17</sup> so an implant that corrects a fixed amount of SA is unlikely to benefit all patients. The patient's corneal SA should be measured preoperatively to properly compensate corneal SA with an implant, and an implant should be selected not only by its power but also by the amount of SA corrected, which is not current clinical practice.<sup>18</sup> Raytracing data on model eyes show that the amount of SA corrected by an implant varies substantially if the anterior chamber depth changes by tenths of millimeters or if the implant is tilted or decentered.<sup>19</sup> Refractive error rarely fluctuates with pupil size,<sup>1</sup> suggesting SA is not a problem in patients with conventional implants. SA increases depth of focus, so reducing it is not always desirable.

## COMA

Coma causes a pencil of rays to “flare out” from the image point in a fashion reminiscent of a comet's tail (Figs. 2.6.5 and 2.6.6). The shape of the wave aberration resembles a lounge chair.

Coma is increased when multiple optical elements do not share the same optical axis. Howland showed that after best spectacle correction, coma accounts for most of the residual aberration in otherwise normal eyes,<sup>20</sup> which is not surprising because none of the ocular media share a common axis.

**Fig. 2.6.6 Coma Spot Diagram.** Coma causes light from a single object point to flare out in the image giving the appearance of a comet's tail.

**Fig. 2.6.7 Distortion.** The original object consists of straight lines (left). Barrel distortion (middle) causes the lines to curve outward. Pincushion distortion (right) causes the lines to curve inward.

Clinically, coma rarely produces recognizable symptoms. However, coma can be symptomatic if there is a large amount present, which can occur (along with other higher-order aberrations) in off-axis keratorefractive surgery, dislocated or tilted crystalline lens or implant, or when the corneal vertex of a full-thickness graft is displaced by an unusual amount.<sup>21</sup>

## DISTORTION

Ideally, the image is geometrically similar to the object, which is to say that the image is a scale model of the object with all image distances proportional to corresponding object distances. Distortion is absent when the transverse magnification is constant over the entire image plane.

In pincushion distortion the transverse magnification increases as distance from the optical axis increases (Fig. 2.6.7). In barrel distortion magnification decreases as distance from the axis increases. Distortion is similar to defocus in that rays still focus stigmatically but in the wrong place. In defocus, rays focus stigmatically but in front or behind the ideal image point. In distortion, rays also focus stigmatically and in the same plane as the ideal image but too far (or too close) to the optical axis.

Pincushion distortion occurs in practically all spectacle-corrected, aphakic patients<sup>22</sup> and is occasionally seen in high myopes after clear lens extraction. Originally, one of the major reasons for the use of intraocular lens implants was to overcome the distortion suffered by spectacle-corrected aphakes. Once common, distortion is now rare since the introduction of intraocular lenses, although there has been a minor resurgence in patients undergoing clear lens extraction.

## FIELD CURVATURE (FC)

Ideally a flat object perpendicular to the optical axis is imaged as a flat object perpendicular to the axis. When field curvature is present, the object is imaged onto a curved surface (as in an IMAX theater). Field curvature

does not become significant until the image is outside the fovea, where retinal acuity is too low to detect the blurring produced by this aberration.

## OBLIQUE ASTIGMATISM (OA)

Oblique astigmatism is not to be confused with regular astigmatism. Seidel only considered rotationally symmetrical optical systems, which excludes regular astigmatism. Like field curvature, oblique astigmatism does not become significant until the image is outside the fovea where retinal acuity is too low to detect the blurring produced by this aberration.

## HIGHER-ORDER ABERRATIONS (HOA)

When the importance of aberration theory began to be appreciated, it was initially thought that understanding in detail the unique characteristics of many individual aberrations would be helpful. Theoretically, an infinite number of aberrations exist, so how many aberrations do clinicians really need to understand thoroughly?

Lens designers have found empirically that 36 aberrations adequately describe the imaging properties of even very complex optical systems. The number of aberrations required for clinical purposes is uncertain but is probably much less. However, lacking clear evidence to the contrary, many authors have adopted the use 36 polynomials based on engineering, not clinical experience.

The order of an aberration is defined rigorously later, but basically an order is a family of aberrations. The clinical triad of myopia, hyperopia, and regular astigmatism all belong to the family of second order wave aberrations. The five Seidel aberrations (coma, SA, FC, distortion, OA) are all fourth order aberrations. As the order increases so does the number of aberrations belonging to the order.

It now appears that besides a general familiarity with aberration theory, a thorough understanding of just a few specific aberrations is sufficient. In addition to defocus and regular astigmatism, the Seidel aberrations of SA and coma and perhaps a few others in specific cases are all that need to be understood in depth.

The situation has returned somewhat, but not completely, to the idea of lumping many aberrations into a single category. Whereas irregular astigmatism refers to any aberration higher than second order, “higher-order aberrations” generally refers to sixth order and above and thus excludes the Seidel aberrations.

In any case, it is clear that typically coma and SA account for most of the eye’s irregular astigmatism, with only small amounts of other aberrations contributing to the total irregular astigmatism. Higher-order aberrations may be increased in pathological cases or after some refractive procedures, particularly keratorefractive surgery.

## CHROMATIC ABERRATION

Wave aberration theory usually adopts the simplifying assumption that the light traversing the optical system is monochromatic. However, chromatic aberration has a significant effect on the image.

Longitudinal chromatic aberration (LCA) is the difference in image location between short and long wavelength light measured along the optical axis (Fig. 2.6.8). LCA is the basis for the duochrome test. The green half of the chart focuses anterior to the red half, and the power of the correcting sphere is adjusted until both sides appear equally sharp. In most cases there is about 0.50 D of separation between the two images.

Transverse chromatic aberration (TCA) is the difference in image location between short and long wavelength light measured in the image plane

(Fig. 2.6.9). Although the chromatic aberration of the eye is significant, color effects are rarely noticeable because of visual processing. Occasionally patients notice colored fringes around the edges of objects or letters when reading; these are usually produced by spectacle lenses made from highly dispersive materials. The problem generally is transient, but if not, can be overcome by using lenses fabricated from less dispersive (i.e., higher Abbe number) materials.

## MEASUREMENT OF OCULAR ABERRATIONS

In 1896 Tscherning was the first to observe irregular astigmatism (in his own eyes).<sup>23</sup> A small, distant source is viewed through a grid of pinhole apertures placed in front of an eye that is or has been rendered myopic (perhaps by fogging with, for example, +5.00 D lens). The grid divides the light into parallel pencils that focus in front of the retina then diverge, forming a pattern on the retina that is essentially the physical embodiment of a spot diagram. The grid will not be regularly spaced if aberrations (other than defocus) are present. If one draws the appearance of the grid, ocular aberrations can be estimated. Readers can easily reproduce this experiment for themselves just as Tscherning did.

As a method for measuring aberrations, the Tscherning aberrometer suffers from the obvious limitation that it is subjective, relying on the patient’s ability to observe and accurately locate the displaced pencils. Nonetheless, it is a useful conceptual tool. The subjective limitations of Tscherning’s approach can be overcome by photographing the grid on the retina. However, photography introduces another problem—double pass. To be photographed, each grid spot on the retina acts as a light source, which passes through the eye, suffering its aberrations a second time. The second pass complicates the analysis of aberrations, although the Allegretto Wave Analyzer is based on this approach.<sup>24</sup>

There are several ways to overcome the double pass problem. One approach is to focus a laser (at low power of course) on the retina.<sup>25</sup> Since the laser traverses only a small amount of the pupil, it is essentially unaffected by ocular aberrations; practically speaking, this is a single pass technique. The small area of laser illuminated retina becomes a source from which light emerges from the eye. If the eye is aberration-free, the emerging light will have planar wavefronts, otherwise aberrations distort the wavefront shape.

Using an approach suggested by Shack, the wavefront is sampled using a lenslet array that focuses small areas of the wavefront onto a detector. Each lenslet produces a small dot image on the detector that is displaced depending on the wavefront’s shape. The full wavefront is reconstructed from the displaced position of dots. The Hartman–Shack, as it is called today, is probably the most reliable way of measuring small amounts of higher-order aberration in an otherwise well-corrected eye or optical system. The technique is not as well suited to the measurement of large amounts of low-order aberrations.<sup>26</sup> Recent modifications of the technique improve the performance for low-order aberrations. Many aberrometers utilize some variation of the Hartmann–Shack approach.

Automated retinoscopy is another means of measuring aberrations and is incorporated into the ARK 10000 (Nidek). The Tracey uses the Tscherning approach but performs it sequentially by scanning a single laser beam over the pupil and observing the beam’s deviation on the pupil.<sup>27</sup> Besides being essentially a double pass system, movements during data acquisition are a potential problem.

It is important to realize that just because an instrument claims to measure aberrations does not mean it actually does so. It is very difficult to verify the accuracy of an aberrometer. Ocular aberrations, especially higher-order aberrations, change with the slightest change in tear film

**Fig. 2.6.8 Longitudinal Chromatic Aberration.** The image formed by short wavelength light is anterior to the image formed by longer wavelengths. This is the basis for the duochrome test used in subjective refraction.

**Fig. 2.6.9 Transverse Chromatic Aberration (TCA).** Highly dispersive materials may produce colored fringes at the image.

thickness, or changes in choroidal thickness that occur during the cardiac cycle, accommodation, hippus, ocular movement, head movement, or fixation change. The active optics photographic system that captures high resolution fundus images requires a bite bar for adequate head stabilization,<sup>28</sup> which no clinical aberrometer utilizes. Too often reproducibility is considered indicative of accuracy, but a stopped watch gives highly reproducible yet useless results. Accuracy cannot be inferred simply because a device gives reproducible results. Given the number of factors that affect ocular aberrations, an instrument that gives highly reproducible results, especially for higher-order aberrations, is suspect. Keep in mind that with all the advances in the clinical measurement of aberrations, there is still no objective measurement of hyperopia, myopia, or regular astigmatism that is consistently superior to subjective refraction. If low-order aberrations cannot be measured satisfactorily by objective methods, good reason exists to suspect that objective measurements of higher-order aberrations are somewhat inaccurate.

Regardless of the method used, all clinical measurements produce a set of discrete data points. The wavefront's shape between data points is not known. Mathematics, no matter how sophisticated, cannot create information beyond that present in the data. To summarize, the mathematical techniques do not find the actual wavefront, only the *most likely* wavefront given the data values, regardless of how the data were acquired (e.g., Hartman–Shack, Tscherning). More data points, provided they are accurately measured, and the more Zernike polynomials considered, the more likely the computed wavefront is a reasonable representation of the actual wavefront.

## Mathematical Considerations

There is no need to be intimidated by the mathematical aspects of aberration theory. Just as a spectacle lens is a combination of spherical and cylindrical contributions, total aberration is the combination of individual aberrations. The only difference is that in aberration theory several more individual aberrations occur, and they are less familiar to clinicians.

An individual aberration can be specified by a graph or its associated formula. As noted, when displayed graphically, the optical axis is rotated 90° from horizontal to vertical. Zernike polynomials are the formulas representing each individual graph.

Every Zernike polynomial has the same structure consisting of a coefficient that specifies the amount of the aberration (analogous to power, but in units of distance, not diopters), a radial polynomial, and usually a sine or cosine function. For instance,

$$\text{Secondary Astigmatism } X = Z_{11}(4\rho^4 - 3\rho^2)\cos 2\theta$$

The coefficient's subscripts (shown in purple) identify the individual aberration, the radial polynomial is  $(4\rho^4 - 3\rho^2)$ , is multiplied by a cosine function. The order of a Zernike polynomial is the sum of the largest exponent in the radial polynomial (red) and the coefficient of  $\theta$  (blue). Thus secondary astigmatism is a sixth order aberration.

Most Zernike polynomials come in pairs. For instance there is another sixth order Zernike polynomial:

$$\text{Secondary Astigmatism } Y = Z_{12}(4\rho^4 - 3\rho^2)\sin 2\theta$$

Note the difference in the coefficient subscripts. The shapes of these polynomials are identical except rotated around the vertical axis (i.e., the optical axis) by 90°.

A few Zernike polynomials are symmetrical about the optical axis and consequently have no trigonometric factor. For instance, fourth order primary spherical aberration is represented by the Zernike polynomial:

$$\text{Primary Spherical Aberration} = Z_{08}(1 - 6\rho^2 + 6\rho^4)$$

Zernike polynomials have only even orders (0, 2, 4, etc.). An order is a family of aberrations. For Zernike polynomials the number of aberrations within an order is always one more than the order itself. Thus there is one 0th order aberration, three 2nd order aberrations, five 4th order aberrations, and so forth. The variables  $\rho$  and  $\theta$  identify the position of a ray in the exit pupil, but it is important to understand the overall concepts without dwelling on mathematical detail.

A Zernike polynomial calculator is available on the Internet.<sup>29</sup> Users choose the amount of each individual Zernike aberration and the total aberration is calculated and displayed, which is a useful tool for those who wish to explore aberration theory in greater detail.

Infinitely, many Zernike polynomials exist, but as a rule, the higher the order of an aberration, the less it contributes to the total aberration. Usually there is no need to consider aberrations higher than a certain order. How many orders of Zernike polynomials must be calculated to obtain a reasonably accurate description of an optical system's aberrations? There is no definite answer, but lens designers have found empirically that 36 Zernike polynomials are sufficient for most purposes. Consequently, clinical aberrometers usually calculate 36 Zernike polynomials, but this is probably excessive. Lens designers usually deal with optical systems far more complicated than the eye. It is likely that far fewer aberrations are required for clinical work, although the precise number is not known, and currently no standard exists.

## AN OVERALL PERSPECTIVE ON ABERRATION THEORY

With the emergence of keratorefractive surgery came the possibility of correcting aberrations uncorrectable by spectacles. Initially some overly optimistic claims were made, including the possibility of achieving 20/6 acuity.<sup>30</sup> These claims were based on an incomplete understanding of aberration theory as well as other optical and nonoptical factors limiting acuity.

It is impossible to correct all aberrations by sculpting a single surface. Lens designers have known for centuries that correcting multiple aberrations requires multiple lenses. For this reason, high-quality optical systems corrected for many aberrations contain multiple lenses. At best, shaping just the anterior corneal surface can correct defocus, regular astigmatism, and SA. Correcting coma by keratorefractive surgery would probably be unwise even if it were possible, because coma is the result of misalignment between cornea and lens. The misalignment changes with age and following cataract surgery and could leave pseudophakic patients worse off.

Wave aberration data measures the entire eye, but keratorefractive surgery alters only the anterior corneal surface. Wavefront guided ablation attempts to improve outcomes by combining aberration data with corneal topography to improve visual results. However, corneal topography data has an accuracy of only  $\pm 5 \mu\text{m}$ , whereas the wavefront optimization requires accuracy better than  $1 \mu\text{m}$ . It appears that at this time corneal topography data is not sufficiently accurate to reap the theoretical benefits of wavefront guidance. Wavefront optimized ablation does not incorporate patient-specific data but simply flattens the ablation profile peripherally to reduce SA. As noted, corneal SA is patient specific, so results will vary.

Altering the shape of just the anterior corneal surface cannot, correct all ocular aberrations. No matter how technically advanced keratorefractive surgery becomes (and it still has a long way to go),<sup>31</sup> it will not be possible to eliminate all aberrations by this method. Even if it were possible to eliminate (or reduce to insignificance) all aberrations, other factors such as diffraction and intraocular light scattering would limit vision.

As noted, aberration theory is strictly limited to geometrical optics, completely ignoring diffraction, light scattering, and many other phenomena that affect visual function. After the correction of defocus and RA, for pupils smaller than about 2.5 mm, acuity is limited by diffraction not aberrations.<sup>32</sup> Consequently, the correction of higher-order aberrations would not lead to further visual improvement in patients with smaller pupils. Aberration theory also ignores intraocular light scattering, which can profoundly affect acuity.<sup>33</sup>

Although incompletely understood, neural mechanisms doubtless play an important role. It is speculative, but patients who have had uncorrected aberrations their entire lives may develop a form of refractive amblyopia, so again correction of irregular astigmatism in adults may not improve vision. Visual processing can decrease the influence of some aberrations but not all. The large amount of chromatic aberration present in most eyes is largely neutralized by visual processing.

In most cases the rays near the edge of the pupil are the most aberrant, in other words, focus farthest from the ideal image point. Wavefront apodization is a general term for any technique that diminishes the effect of peripheral rays on the image reducing the influence of aberrations. For example, rays striking the retina parallel to the photoreceptor outer segments produce more of a response than oblique incident rays (the Stiles–Crawford effect).<sup>34</sup> The Stiles–Crawford effect mitigates the influence SA and many higher-order aberrations.

For various reasons, apodization also can diminish image quality. Apodization is helpful provided the improvement in image quality gained by decreasing the influence of aberrations exceeds the loss of image quality produced by the apodization itself. Given the natural retinal apodization, the advantages of wavefront apodized IOLs may not be significant

or even beneficial. Keratorefractive surgery often increases HOA. The Stiles–Crawford effect may to some extent reduce the effect of HOA on vision-improving refractive outcomes.

Clinicians should be aware that irregular astigmatism is not uncommon but actually ubiquitous. All eyes have a large amount of uncorrected chromatic aberration. Considering only monochromatic aberrations, after correction of sphere and cylinder, almost all eyes will have some residual uncorrected irregular astigmatism. In most cases, coma is the dominant uncorrected aberration followed by SA to a lesser extent.

Aberration theory and wavefront methods were developed in the hope of improving the visual outcomes of keratorefractive surgery by correcting higher-order aberrations. Ironically, wavefront measurements have shown that more often than not keratorefractive surgery introduces more higher-order aberration than it corrects.<sup>35–37</sup>

# Current Concepts, Classification, and History of Refractive Surgery

## 3.1

*Suphi Taneri, Tatsuya Mimura, Dimitri T. Azar*

**Definition:** Refractive surgery is the surgical correction of refractive errors of the eye such as myopia, hyperopia, astigmatism, and presbyopia.

### Key Features

- Established subspecialty of ophthalmology.
- Growing variety of well-established procedures.
- Adequate understanding of potential surgical complications, limitations, and alternatives.
- Blurring boundary with cataract surgery.

### Associated Features

- Alterations in optical aberrations after surgery.
- Mean uncorrected visual quality after modern procedures similar to preoperative spectacle correction.

## INTRODUCTION

Refractive surgery is one of the most rapidly evolving fields in ophthalmology. The introduction of the excimer laser, for example, has replaced corneal incisions for routine cases in a very short time. Additionally, over the past decade the femtosecond laser for laser-assisted in situ keratomileusis (LASIK) has added to the ease, safety, and efficacy of refractive procedures. Today, the femtosecond laser also is used for:

- Incisional refractive surgery.
- Corneal tunnels or pockets for the insertion of ring segments or disc-shaped implants into the stroma.
- Lamellar or penetrating corneal transplantations.
- Removal of corneal stromal lenticule to change the refraction of the eye small incision lenticule extraction (SMILE).
- (Refractive) lens exchange surgery.

Many new approaches to correct presbyopia have been introduced in the last couple of years, including laser ablation profiles and intracorneal and intraocular implants. The greatest paradigm shift may have been the Nobel prize-winning method for adjusting the refractive power of an intraocular lens (IOL) after implantation into the eye by targeted radiation with UV light. Corneal cross-linking for the treatment of keratoconus is now a Food and Drug Administration (FDA)-approved treatment that also may have some potential as a refractive procedure.

In this chapter, we discuss excimer laser and ablation profiles; the classification of the different refractive surgery procedures, their utilization, advantages, and limitations; and briefly describe new procedures.

## EXCIMER LASER AND ABLATION PROFILES

Excimer laser corneal surgery was introduced as a precise tool for linear keratectomies by Trokel et al.<sup>1</sup> in 1983 but was later used for corneal reprofiling or photorefractive keratectomy (PRK) in 1988.<sup>2</sup> The ultraviolet laser (193 nm excimer or 213 nm solid state) allows the anterior corneal surface to be reshaped precisely to change its radius of curvature<sup>3</sup> (Fig. 3.1.1).

Numerous technological developments—such as flying-spot lasers, eye trackers, and use of femtosecond lasers for flap preparation—have

**Fig. 3.1.1 Photorefractive Keratectomy (PRK).** After removal of the corneal epithelium, the excimer laser is used to reprofile the anterior curvature of the cornea, which changes its refractive power.

improved clinical outcomes.<sup>4</sup> The advent of wavefront measurement technology also enabled the quantification of ocular aberrations.<sup>5</sup>

## Laser Ablation Profiles

The excimer laser can be used to flatten or steepen differentially the corneal meridians and hence to treat compound myopic and compound hyperopic astigmatism. Mixed astigmatism can be treated by flattening the refractively more powerful meridian or by steepening the weaker one.

There are currently several ablation profiles available for laser vision correction. Challenging cases include high and mixed astigmatism, higher degrees of defocus, large pupil size, higher amounts of higher-order aberration (HOA) or specifically spherical aberrations, thin corneas, pre-existing corneal opacification, or night driving problems. Assessment and treatment of an eye may be complicated by previous corneal or lenticular surgery leading to false measurements or an unpredicted response to the ablation. Moreover, a refractive procedure may have therapeutic aspects in recurrent erosion syndrome.

Existing laser ablation profiles include<sup>6</sup>:

- Munnerlyn's formula.<sup>7</sup>
- Wavefront-guided ablation.
- Wavefront-optimized or aspherical or Q factor-adjusted laser profile.
- Topography-guided ablation.
- Presbyopia correcting profiles.

In addition, combinations of these existing variants have been introduced recently, and even more are announced for the future (for example, ray-tracing optimized ablations).<sup>8</sup> Ablation profiles in corneal laser surgery

can be divided into those based on the total optical system and those based on the cornea.<sup>9</sup>

## Munnerlyn's Formula

The classic ablation profile for the correction of myopia and myopic astigmatism is based on Munnerlyn's formula,<sup>7</sup> which removes a convex-concave lenticule of corneal tissue with spherocylindrical surfaces to remodel the corneal curvature. The laser profile is based only on subjective and objective measurements of refraction. It does not take spherical aberrations into account, which may lead to an increase of spherical aberration, resulting in an oblate cornea. Munnerlyn's formula does not compensate for the loss of fluence in the periphery of the ablation zone, which occurs because the energy of a laser pulse is spread out over a larger area (i.e., an oval rather than a circle), nor the increased reflectance of the laser beam due to an oblique angle of incidence when the laser is not targeting the corneal apex.<sup>10</sup> Moreover, the reduction in tissue removal is greater than the reduction in fluence. These three laser-related factors together with different biomechanical and wound-healing responses in the periphery are now compensated for by algorithms proprietary to the laser manufacturer.

## Wavefront-Guided Ablation

The principles of wavefront deformation measurements are discussed in greater detail in Chapter 3.6. In a perfect optical system, all the refracted rays are focused on a single plane (wavefront). Optical aberrations induce deformations on this plane and can be quantified. They represent the optical performance of the entire visual system, not only the anterior surface of the cornea, as in corneal topography. The lower-order optical aberrations (sphere and astigmatism) can be corrected with spherocylindrical glasses. The HOA (including spherical aberration and coma) correspond to what is clinically known as irregular astigmatism (Fig. 3.1.2).

In theory, the higher the amount of HOA, the greater the benefit of performing a wavefront-guided ablation. However, wavefront-sensing may be negatively affected by the use of mydriatic eyedrops.<sup>11</sup> Furthermore, new HOA are induced by the laser treatment itself even if the radial loss of efficacy is compensated by less than perfect alignment of the ablation pattern on the cornea<sup>12</sup> and less than perfect eye-tracking,<sup>13</sup> including cyclo-torsional movements<sup>14</sup> before and during ablation. In addition, aberrations are induced when a LASIK flap is created.

Lenticular aberrations increase with age, whereas corneal aberrations remain fairly stable throughout our lives in the absence of anterior corneal disease or dry eye.

## Topography-Guided Ablation

Based on topography measurements by different topographers, including the Orbscan IIz (Fig. 3.1.3), the Pentacam (Fig. 3.1.4), and others, the elevation profile of the anterior corneal surface is calculated. The desired corneal surface is determined with the goal of correcting the refractive error and HOA induced at the cornea. The difference between the preexisting surface and the desired surface is used to calculate the ablation profile. Because of the calculated wavefront component of the cornea in this laser profile, the term *corneal wavefront ablation* is sometimes imprecisely used.

Topography-guided ablations have their greatest theoretical superiority in cases in which the problem is clearly located in the anterior cornea, like consequences of earlier surgery.<sup>15,16</sup> Examples include decentered laser ablations,<sup>17</sup> corneal grafts,<sup>15</sup> and corneal scars.<sup>18</sup> The reason is that a corneal topographer has a much higher resolution than wavefront sensors. A corneal topographer may evaluate the whole cornea, whereas ocular aberration measurements are only possible over the entrance pupil. Finally, a topographer directly evaluates the surface on which there are imperfections. Topography-guided ablations that were combined with collagen cross-linking were introduced in the treatment of keratoconus<sup>19</sup> or forme fruste keratoconus.<sup>20</sup>

### Wavefront-Optimized<sup>21</sup>/Aspherical<sup>22</sup>/Q-Factor-Adjusted<sup>23–25</sup> Laser Profiles

The term *wavefront-optimized* refers to laser treatment software that has been designed with certain corrections preprogrammed, although a true and customized wavefront plan is not employed. Spherical aberrations are the most disturbing optical imperfections after the lower-order terms *sphere* and *cylinder*. Because standard spherocylindrical excimer ablations induce positive spherical aberrations,<sup>26,27</sup> wavefront-optimized laser profiles have been developed to preserve the eye's pre-existing optical aberrations without introducing new aberrations.<sup>28,29</sup>

The aim of preserving the natural cornea shape of each patient is propagated by other companies as aspherical or Q factor-adjusted ablation. This treatment is designed to improve the eye's optical quality by optimizing the asphericity of the cornea. The Q-factor is a measure of the asphericity of the cornea. In the normal population, the mean Q-factor is  $-0.25$ , which indicates a slightly prolate shape. After determining the ideal asphericity of the cornea in a model, some researchers have suggested the optimum Q-factor should be around  $-0.4$  or  $-0.5$ .<sup>30</sup>

### Presbyopia Correction

Presbyopia correction can be attempted by creating multifocal corneas<sup>31</sup> or hyperprolate corneas when aiming for a postoperative Q-factor close to  $-1.0$ . Attempts to address presbyopia by corneal ablation date back to the last millennium.<sup>32</sup>

## CONCEPTS IN DEVELOPMENT

An online pachymetry-guided ablation could aid in removing the anterior portion of the cornea without perforating Descemet's layer before a lamellar graft is transplanted.

In routine laser vision correction, the combination of existing principles will bring even better outcomes than we are used to today. Such a combination of a wavefront-guided ablation with an aspherical profile according to the cornea's preoperative asphericity has delivered excellent results in our hands.<sup>33</sup> Optical ray-tracing algorithms, on the other hand, may allow the highest degree of customization. The idea behind ray tracing is that no single measurement of an eye can provide all the data required to achieve utmost individualization of the ablation. Therefore the information of several types of measurements such as ocular wavefront, corneal topography including the topography of the cornea's back surface, corneal thickness, anterior chamber depth, lens thickness, and axial length may be considered. The systematic induction of HOA by means of wavefront-guided treatments may be overcome by such a method.<sup>8</sup>

## CLASSIFICATION OF REFRACTIVE PROCEDURES

The refractive power of an optical system, such as the eye, can be modified by changing the curvature of the refractive surfaces, the index of refraction of the different media, or the relative location of the different elements of the system.

Several classifications of keratorefractive surgery have been proposed based on the mechanisms of action of the surgery<sup>34</sup> or on the type of surgery.<sup>35</sup> A simplified classification in which the site of action of the surgery on the cornea—either over the optical zone or peripheral to it—is matched against the four different mechanisms of action of corneal surgery: addition, subtraction, relaxation, and coagulation-compression. The procedures that act on the optical zone are further subdivided into superficial or intrastromal (Table 3.1.1). In addition to keratorefractive surgery, the use of intraocular implants is the second class of procedures to modify the ocular refraction.

### Cornea

Approximately two-thirds of refraction occurs at the air-tear-corneal interface, which generally parallels the anterior surface of the cornea. The cornea is readily accessible, and its curvature can be modified as an extraocular procedure. Most keratorefractive procedures to date modify the radius of curvature of the anterior surface of the cornea.<sup>36</sup>

#### Central Cornea

Most procedures used to modify the corneal optical zone, or central cornea, change the relationship between its anterior and posterior surfaces; the thickness of the cornea is also modified. The central cornea may be modified either on the surface or intrastromally.

TABLE 3.1.1 Proposed Classification of Keratorefractive Surgical Procedures

Optical Zone	Addition	Subtraction	Relaxation	Coagulation–Compression
Superficial	Epikeratophakia Synthetic epikeratophakia	PRK, LASEK, epiLASIK, epi-Bowman keratectomy		Corneal molding
Intrastromal	Keratophakia Intracorneal lenses Intracorneal transplants	LASIK, Femto-LASIK Keratomileusis in situ Keratomileusis SMILE	Lamellar keratotomy	
Peripheral cornea	Intracorneal ring segments	Wedge resection	Radial keratotomy Hexagonal keratotomy Arcuate keratotomy	Thermokeratoplasty Compression sutures

LASEK, Laser subepithelial keratomileusis; LASIK, laser-assisted in situ keratomileusis; PRK, photorefractive keratectomy; SMILE, small incision lenticule extraction.

Fig. 3.1.5 Subepithelial Haze 3 Months After LASEK in a 28-Year-Old Man.

### Corneal Surface: Addition

**Epikeratophakia.** Epikeratophakia (also known as epikeratoplasty and onlay lamellar keratoplasty) was introduced by Werblin et al.<sup>37</sup> It involves removal of the epithelium from the central cornea and preparation of a peripheral annular keratotomy. A lyophilized donor lenticule (consisting of Bowman's layer and anterior stroma) is reconstituted and sewn into the annular keratotomy site.

Use of epikeratoplasty for the general treatment of myopia and hyperopia has been abandoned largely because of the potential loss of best-corrected visual acuity due to complications like irregular astigmatism, delayed visual recovery, and prolonged epithelial defects.

Synthetic materials<sup>38</sup> and improved means of attaching the lenticule to the cornea may allow epikeratoplasty to become a more useful refractive technique in the future.

### Corneal Surface: Subtraction

The surface ablation procedures PRK, laser subepithelial keratomileusis (LASEK), and epiLASIK have excellent results in terms of safety, efficacy, and stability with low-to-moderate myopic astigmatic corrections.<sup>39</sup> In prospective trials, no clinically significant superiority of any of these three methods could be established regarding epithelial closure time, pain perception, haze formation, safety, and efficiency.<sup>40</sup> Epi-Bowman keratectomy (EBK) is the latest variant of these surface ablation techniques.

**Photorefractive Keratectomy.** In PRK, the epithelium is removed by mechanical scraping, utilizing ethanol or with an excimer laser ablation, before the stroma is ablated to correct the ametropia. The stroma is eventually covered by the epithelium, which heals from the periphery toward the center in about 4 days. After PRK, the corneal epithelium undergoes a hyperplastic phase in which the refractive status of the eye may be modified.<sup>41</sup> The deposition of new collagen and glycosaminoglycans<sup>42</sup> by activated stromal keratocytes after PRK is a common phenomenon after deep ablations and in younger individuals (Fig. 3.1.5) and manifests as corneal haze or subepithelial scarring. The activation of the keratocytes seems to stem from interaction of epithelial cells and raw corneal stroma as the epithelium migrates to cover the defect or from activation of keratocytes by soluble tear factors that percolate through the initial epithelial defect after PRK. The haze may be associated with regression of the refractive

effect or focal topographical abnormalities; it peaks in humans 3–6 months after the operation and disappears after 1 year for most patients. Many surgeons now use mitomycin-C prophylactically during the initial treatment to prevent haze formation or therapeutically to remove haze.<sup>43</sup>

**Laser Subepithelial Keratomileusis.** LASEK involves cleaving the epithelial sheet at the basement membrane or at the junction of the epithelium to Bowman's membrane with dilute alcohol, applying the laser as in conventional PRK, and repositioning the epithelium afterward.<sup>44,45</sup> The first LASEK procedure was performed by Azar.<sup>46,47</sup> The term LASEK was coined by Massimo Camellin, who also popularized this method of surface ablation.

**EpiLASIK.** EpiLASIK is an abandoned surface ablation procedure designed to create an epithelial flap with an epikeratome that is equipped with a blunt separator instead of a sharp blade, as in microkeratomes used during LASIK.

**Epi-Bowman Keratectomy (EBK).** Epi-Bowman keratectomy was recently introduced and does not employ a metallic blade but a soft instrument to manually remove the epithelium before stromal ablation.

### Corneal Stroma: Subtraction

**Keratomileusis.** The term *keratomileusis* refers to the technique of “carving” (Greek *smileusis*) the cornea. Dr. José I. Barraquer first reported clinical results with the technique in 1964.<sup>48</sup>

Classic keratomileusis involves the excision of a lamellar button of parallel faces from the cornea with a microkeratome, freezing and reshaping the lamellar button, and replacing it in position with sutures. The procedure was modified by Krumeich and Swinger, who reshaped the disc with a second microkeratome pass without having to freeze it, in a procedure known as BKS (Barraquer–Krumeich–Swinger) keratomileusis. Ruiz and Rowsey<sup>49</sup> made further modifications by applying the second microkeratome pass to the stromal bed instead of the resected disc, in a procedure called in situ keratomileusis. Even though the refractive cut with the microkeratome gave a disc of parallel surfaces with no optical power, a dioptric effect was achieved because of the remodeling of corneal tissue, as described by Barraquer<sup>50</sup> in the law of thickness. The development of a mechanized microkeratome, or automatic corneal shaper, provided a more consistent thickness and diameter of the corneal disc and improved the predictability of the procedure. This procedure is known as automated lamellar keratoplasty (ALK). The fact that the corneal cap does not have to be modified led to the use of a hinged flap instead of a free cap. This, in turn, led to sutureless repositioning of the flap, which simplified the procedure further.

**Laser-Assisted in situ Keratomileusis.** LASIK refractive correction is the most commonly performed refractive surgery in the world today. The early model was first performed in rabbits by Pallikaris et al.<sup>51</sup> in a modification of Ruiz's keratomileusis in situ (Fig. 3.1.6). Buratto and Ferrari<sup>52</sup> first performed this procedure in humans after inadvertently obtaining a thin resection with the microkeratome while performing a modification of Barraquer's classic keratomileusis using the excimer laser instead of the cryolathe to modify the corneal cap.

In PRK, LASEK, and epiLASIK the laser is applied directly to Bowman's layer, whereas in LASIK it is applied to the midstroma after a flap has been lifted from the cornea. The flap is then replaced. LASIK causes a minimal degree of epithelial hyperplasia (much less than PRK) that causes regression of the effect.<sup>53</sup> No visually significant haze follows uncomplicated LASIK,<sup>54</sup> but when the flap is too thin, haze may occur, suggesting that a critical amount of unablated flap keratocytes is needed to inhibit haze formation after routine LASIK.

**Femto-LASIK.** Traditionally, the corneal flap cut during LASIK was created with a microkeratome blade. In contrast, Femto-LASIK uses the

**Fig. 3.1.6 Laser-Assisted in situ Keratomileusis (LASIK).** A flap with parallel sides is lifted using the microkeratome. The excimer laser is used to remove an exactly planned amount of tissue from the exposed corneal stroma. The flap, with its intact epithelium, is then folded back, and as it drapes over the modified stromal surface, the refractive power of the anterior corneal surface is modified. The dotted area in the bottom panel corresponds to the stromal tissue that was removed. No sutures are required.

femtosecond laser, which is coupled to the patient's eye with an interface fixated by suction. The femtosecond laser beam separates the corneal tissue by causing numerous microexplosions at a preprogrammed depth and position. The remaining tissue bridges between these cavitation bubbles are then bluntly dissected using spatula-like instruments. As no actual cut is performed with the femtosecond laser, in the rare event of a suction loss during flap preparation, a second attempt can be done immediately. This is not possible after a suction loss of a mechanical microkeratome, which necessitates changing to a surface ablation or waiting for approximately 3 months. This feature is a clear advantage to mechanical microkeratomers, but other flap-related complications like buttonholed flaps, flap striae, flap dislocation, and keratectasia may still happen. Transient light sensitivity—a new complication seen with initial femtosecond flap makers that occurred in some patients and resolved spontaneously after a couple of weeks—seems to be overcome with state-of-the-art femtosecond lasers by reducing the amount of energy delivered into the cornea.

**Intrastromal Laser Ablation.** Intrastromal, solid-state, picosecond lasers are being developed that are more compact and portable than excimer lasers. Intrastromal ablation is made to flatten the central cornea, the epithelium and Bowman's layer are spared, and thus fewer keratocyte fibroblastic responses are seen.

**Intrastromal Lenticule Extraction.** A new procedure, small incision lenticule extraction (SMILE), takes place entirely within the cornea and is performed exclusively with a femtosecond laser system, that is, no excimer laser is needed. The SMILE procedure consists of these steps (Fig. 3.1.7):

- The femtosecond laser is used to outline a small lens-shaped segment of tissue (lenticule) within the center of the cornea and a small incision in the midperiphery of the cornea.
- The lenticule is removed through this self-sealing incision and discarded.

The removal of the lenticule reduces the curvature of the cornea, thereby reducing myopia. Without a corneal flap, SMILE causes less postsurgical dry eye and may pose less risk for ectasia than LASIK. Also, without a corneal flap, no risk exists of flap displacement from trauma to the eye after surgery. SMILE has recently been approved by the FDA for the correction of myopia and myopic astigmatism and may soon become a popular alternative to LASIK for vision correction. However, currently it is not possible to perform SMILE for hyperopia.

### Corneal Stroma: Addition

**Keratophakia.** Keratophakia is the technique by which a corneal lens is inserted to change the shape of the cornea and modify its refractive power.<sup>55</sup> Traditionally, a lamellar keratectomy was performed with a microkeratome on the recipient's cornea. A fresh or preserved donor cornea also underwent a lamellar keratectomy. A stromal lens was created from the donor cornea and placed intrastromally in the recipient. In the future, lenticules obtained during a SMILE procedure may be reshaped according to the refractive needs of the recipient cornea and implanted in an intrastromal interface created by a femtosecond laser.

**Intracorneal Inlays.** Intracorneal inlays may prove beneficial in the treatment of various refractive errors. Barraquer, working in Bogotá, Colombia, performed experiments with corneal implants as early as 1949. Early inlays were composed of flint glass and Plexiglas for the correction of aphakia and high myopia. Claes Dohlman first described the use of a permeable lenticule in 1967 in Boston. Hydrogel inlays were developed so as not to impede metabolic gradients across the stroma, including nutrient flow to the anterior cornea.

Today, corneal inlays mainly are designed to treat presbyopia. The mechanisms behind the current generation of inlays can be divided into three categories:

- Small-aperture corneal inlays that increase the depth of focus.
- Space-occupying inlays that create a hyperprolate and thus multifocal cornea.
- Refractive annular addition lenticules that work as bifocal optical inlays to create separate distance and near focal points.

### Corneal Stroma: Relaxation

#### **Lamellar Keratotomy (Hyperopic Automated Lamellar Keratoplasty).**

In deep lamellar keratotomy (hyperopic ALK), a microtome performs a deep keratectomy to elevate a corneal flap that is replaced without additional surgery. The stromal bed then develops ectasia under the flap. Hyperopic ALK works best for low levels of hyperopia, but the predictability is low, and the risk of progressive ectasia ended the use of this procedure.

### Peripheral Cornea

Several keratorefractive procedures are used to change the shape of the central cornea through their action on the peripheral cornea. This is achieved without changing the thickness or the relationship between the anterior and posterior surfaces over the corneal optical zone.

### Peripheral Cornea: Addition

**Intracorneal Rings.** Krumeich<sup>56</sup> introduced the concept of titanium rings to alter the corneal curvature in keratoconic eyes or in combination with corneal transplant surgery (Fig. 3.1.8). In keratoconic eyes, first, a dedicated trephination system (GTS) is used to create a circular groove in which the ring is placed and secured with a double running antitorque suture. The suture may be removed after completion of wound healing. The rings may be inserted in the interface of corneal transplants. The idea was to modify corneal curvature by altering the shape of the implanted ring with special instruments. However, this concept yielded no sufficiently predictable effect, and extrusion of the rings has been observed.

**Intracorneal Ring Segments.** Intracorneal ring segments are placed in the peripheral cornea and take advantage of the fact that the arc of the cornea remains constant at all times, so when the anterior surface is lifted focally over the ring, a compensatory flattening of the central cornea occurs (Fig. 3.1.9). An advantage of intracorneal segments over other refractive surgical techniques is removability as opposed to reversibility, as at least the tunnel preparation is permanent. The main drawbacks are the limited range of correction and poor predictability compared with excimer laser ablative procedures. As a result, intracorneal ring segments today are almost solely used for high cylindrical corrections in keratoconic corneas and may be combined with corneal cross-linking.

### Peripheral Cornea: Subtraction

**Wedge Resection.** Troutman developed the use of wedge resections and resuturing in the flat meridian, often with relaxing incisions in the steep meridian. Although the procedure effectively decreases astigmatism, clinical results are highly unpredictable and it is now reserved for the correction of postkeratoplasty astigmatism of high degree. The use of the femtosecond laser to facilitate wedge resection surgery has been shown to be effective for postkeratoplasty astigmatism.

**Fig. 3.1.7 Small Incision Lenticule Extraction (SMILE).** A femtosecond laser fashions an intrastromal corneal lenticule. This lenticule is extracted through a small incision that flattens the anterior corneal surface. No flap and sutures are required.

**Fig. 3.1.8 Intracorneal Titanium Ring as Devised by Krumeich.**

#### Peripheral Cornea: Relaxation

**Radial Keratotomy.** Radial keratotomy (RK) for myopia involves deep, radial corneal stroma incisions that weaken the paracentral and peripheral cornea and flatten the central cornea (Fig. 3.1.10). Sato et al.<sup>57</sup> in Japan used anterior and posterior corneal radial incisions to treat keratoconus,

**Fig. 3.1.9 Intracorneal Ring Segments.** After a peripheral circular lamellar dissection, two polymethyl methacrylate ring segments of predetermined diameter and thickness are inserted. The midperipheral anterior lamellae are lifted focally by the ring segments, which results in a compensatory flattening of the central anterior lamellae and hence a decrease in the refractive power of the central cornea.

**Fig. 3.1.10 Radial Keratotomy.** Partial-thickness incisions result in limited ectasia of the paracentral cornea and compensatory flattening of the central cornea.

astigmatism, and myopia. The procedure was abandoned because of the long-term complication of bullous keratopathy secondary to endothelial cell loss.<sup>58</sup> Anterior RK was performed by several ophthalmologists in the former Soviet Union in the early 1970s and was later popularized by Fyodorov and Durnev.<sup>59</sup> RK has been performed in the United States since 1978.<sup>60</sup>

The stability of refraction after RK is lower than with many other refractive surgical procedures. Therefore RK has been replaced by excimer laser procedures.

**Hexagonal Keratotomy.** Proposed by Gaster and Yamashita in 1983, hexagonal keratotomy, first performed in humans by Mendez in 1985, consists of making circumferential, hexagonal, peripheral cuts around a clear optical zone. It “uncouples” the central cornea from the periphery, which allows the cornea to bulge or steepen, thereby decreasing hyperopia. The

procedure has been largely abandoned because of the complications of poor healing and irregular astigmatism.<sup>61</sup>

**Astigmatic Keratotomy.** The first modern cataract extraction through a corneal incision, performed by David in France in 1747, introduced ophthalmologists to surgically induced astigmatism. Several investigators in the latter part of the nineteenth century, including Snellen, Schiötz, and Bates, attempted to correct corneal astigmatism with transverse relaxing corneal incisions. The first systematic study of the correction of astigmatism was performed by Lans<sup>62</sup> in 1898.

Astigmatic keratotomy (AK) involves making transverse cuts in an arcuate or straight fashion perpendicular to the steep meridian of astigmatism to produce localized ectasia of the peripheral cornea and central flattening of the incised meridian, thereby decreasing the astigmatism. Although important in its time, AK is no longer used except during a corneal graft.

For cataract surgery, limbal-relaxing incisions have gained popularity because they are more comfortable for the patient than are arcuate or transverse midperipheral incisions, although their effect is smaller as they are farther away from the corneal center.<sup>63</sup> However, today limbal-relaxing incisions are inferior to the implantation of toric IOLs during cataract surgery.

### Peripheral Cornea: Coagulation–Compression

**Thermokeratoplasty.** Radial intrastromal thermokeratoplasty shrinks the peripheral and paracentral stromal collagen to produce a peripheral flattening and a central steepening of the cornea to treat hyperopia. Unable to produce satisfactory results with relaxing incisions, Lans used cautery to selectively steepen a corneal meridian in rabbits. It was not until 1914 that Wray performed the procedure in humans in a case of hyperopic astigmatism. The procedure was later modified to correct hyperopia and popularized by Fyodorov. Although an initial reduction in hyperopia was observed, the lack of predictability and significant regression are persistent problems.

The solid-state infrared laser holmium:yttrium–aluminum–garnet (Ho:YAG) laser has been used in a peripheral intrastromal radial pattern (laser thermokeratoplasty) to treat hyperopia of 2.50 diopters (D) and less.<sup>64</sup> The long-term refractive stability of Ho:YAG laser thermokeratoplasty is poor. A handheld radiofrequency probe to shrink the peripheral collagen also has been employed.

**Microwave-Induced Thermokeratoplasty: Keraflex Procedure.** During an investigational Keraflex procedure, a microwave generator delivers a single low-energy microwave pulse lasting less than 1 second. Energy is applied to the cornea using a dielectrically shielded microwave emitter that contacts the epithelial surface. Through capacitive coupling, the single pulse raises the temperature of the selected region of corneal stroma to approximately 65°C, shrinking the collagen and forming a toroidal lesion in the upper 150  $\mu$ m of the stroma. The lesion created is intended to flatten the central cornea to achieve myopic correction without compromising the biomechanical integrity of the cornea.

**Circular Keratorrhaphy.** A suture placed in a circular fashion on the peripheral cornea to constrict the cornea and steepen the central cornea was first attempted by Krasnov in Russia in 1985 to treat hyperopia and aphakia. The principal problems are the development of irregular astigmatism by differential tension and loss of the effect as the suture elongates and “cheese-wires” through the tissue.

### Peripheral Cornea: Oppression

**Orthokeratology.** Orthokeratology is used as a nonsurgical option for the correction of myopia. An orthokeratology lens is flatter, looser, and larger than a conventional lens. Theoretically, the lens mechanically alters the central corneal contour over time.<sup>65,66</sup> Because of safety concerns, orthokeratology did not gain widespread acceptance.

Reverse-geometry lenses are fitted with a base curve flatter than the central corneal curvature to apply pressure to a central corneal zone that flattens during wear to reduce the myopic refractive error. The current approach to orthokeratology using reverse-geometry lens designs results in rapid reductions in myopic refractive error.<sup>67–71</sup>

## Intraocular Lenses and Refractive Lensectomy

### Refractive Lens Exchange

Extraction of the clear lens to correct high myopia was performed by Fukala<sup>72</sup> in Germany in 1890. The procedure was later abandoned because of an unacceptably high rate of complications. With more sophisticated operative techniques, recently there has been renewed interest in managing

high refractive errors by clear lens extraction. Because of retinal problems in high myopes, the procedure seems safer in high hyperopes.<sup>73</sup> For young patients, one major drawback is the loss of accommodation. To date, a variety of methods to restore near vision are available after lens removal, including correction with glasses and contact lenses, monovision, scleral expansion techniques, and various IOLs. However, none of them is perfect.

### Toric Intraocular Lenses

Intraocular lenses with a toric or bitoric surface with corrections of up to 5 D to correct even high amounts of astigmatism are available. They have demonstrated reasonable rotational stability.

### Multifocal Intraocular Lenses

Pseudoaccommodative bifocal or trifocal lenses with a refractive and/or diffractive design have been in routine refractive surgical use for the last couple of years. For acceptable correction of presbyopia, the achieved refractive error must be negligible. However, this is often not the case after lens exchange alone even with toric multifocal IOLs, and the use of modern biometry devices, as well as sophisticated lens power calculation formulae. Then an enhancement with an excimer laser may be an option. However, even if emmetropia is achieved, compromises in night vision, glare, and halos remain inherent drawbacks of this approach.

### Potentially Accommodative Intraocular Lenses

An alternative approach to a true accommodative IOL is to use the “focus shift” principle produced by an increase in effective lens power with forward movement of the optic.<sup>74–76</sup> The haptics of the accommodative IOL fixate in the capsular bag and allow the optic to move in reaction to the contraction of the ciliary muscle so that the patient can focus on nearby objects (Fig. 3.1.11). However, based on simple calculations, the forward shift possible in the capsular bag on its own is not sufficient to allow for the restoration of a reasonable amount of accommodation of 2–3 D for a single optic lens.

Another variant is to combine two optics that move relative to each other within the capsular bag into a single IOL (Synchrony dual-optic lens, Abbot Medical Optics, AMO, Santa Ana, CA). Using this intraocular telescope effect, small excursions may allow for sufficient accommodative response. The FluidVision IOL (PowerVision, Belmont, CA) uses liquid channels to harness the accommodative forces from the ciliary body expressed through the capsule similar to the crystalline lens. The NuLens (NuLens, Ltd., Herzliya Pituah, Israel) is a two-piece IOL that is placed outside the capsular bag. With the Tetraflex lens (Lenstec, St Petersburg,

**Fig. 3.1.11 Potentially Accommodative Intraocular Lens, “Crystalens.”** The IOL is fixated in the capsular bag. Forward movement or change in shape of the IOL in reaction to the contraction of the ciliary muscle may have an accommodative effect.

**Fig. 3.1.12** Angle-Supported Anterior Chamber Phakic Lens (© 2017 Novartis).

FL) the rationale is that accommodation results from an increase in HOA caused by deformation of the IOL through ciliary muscle contraction and/or increased vitreous pressure analogous to the natural lens. However, no long-term data are available yet for any of these potentially accommodating IOLs.

### Light-Adjustable Intraocular Lenses

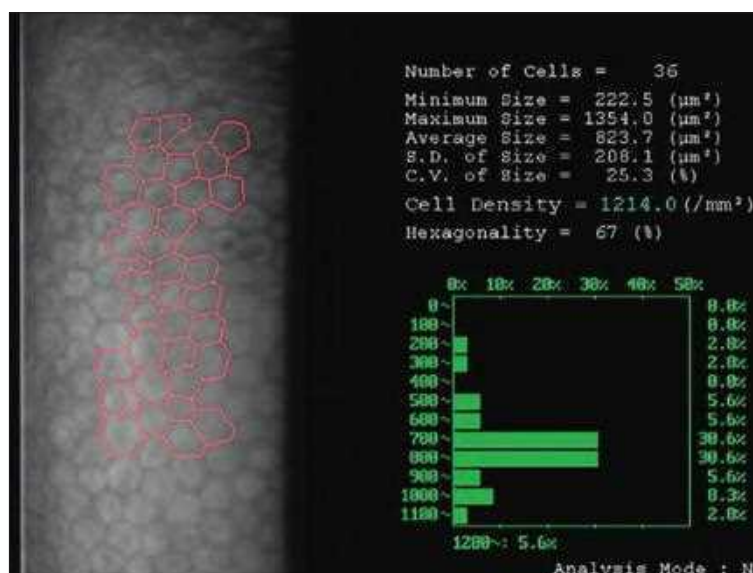

The Light Adjustable Lens (LAL, Calhoun Vision, Pasadena, CA) utilizes a Nobel prize-winning technology that allows it to change its refractive power after implantation in the eye. The LAL has properties similar to standard monofocal IOLs, but it differs with the special macromers incorporated in the makeup of the lens. These macromers are sensitive to light of a certain wavelength. When irradiated by such light, the macromers are photopolymerized.

After LAL implantation using a standard cataract surgery technique, allowing 2–3 weeks for corneal incisions to heal and refraction to stabilize, the lens in the eye will be irradiated for approximately 2 minutes with a digital light delivery device specially designed to deliver the exact dose and profile of light onto the lens. This light exposure is limited to certain portions of the lens and lets the macromers form an interpenetrating network via photopolymerization. Over the next 1–2 days, unreacted macromers from the nonexposed areas physically migrate to the irradiated areas, thus re-establishing a chemical equilibrium. This physical diffusion causes the irradiated parts to swell and change their curvature, which results in a change of refractive power. Myopia, hyperopia, and astigmatism may be corrected by customized irradiation patterns. Even multifocal treatments or the induction of positive or negative asphericity are thus possible. Once the targeted power adjustment is achieved, the entire lens is irradiated to polymerize the remaining unreacted macromers.

### Phakic Intraocular Lenses

In the 1950s, the use of phakic IOLs was attempted first by Strampelli and Barraquer but abandoned at that time because of multiple complications. Improvements in IOLs have renewed interest in the procedure. The iris-claw lens originally devised by Worst for the correction of aphakia was later modified by Fechner et al.<sup>77</sup> to correct high myopia in phakic patients. It is enclaved in the midperipheral, less mobile iris and presently requires a 6.0-mm incision for its insertion. The angle-supported phakic IOL was introduced by Baikoff and Joly<sup>78</sup> for the correction of myopia and has gone through several modifications (Fig. 3.1.12). Long-term follow-up has reported progressive pupil ovalization with an older model.<sup>79</sup>

The posterior chamber phakic IOL was introduced by Fyodorov et al.<sup>80</sup> in 1990. Several new models have been developed since. They must accommodate to the space between the posterior iris and the crystalline lens. Sizing is crucial. If the IOL vaults too much, pigment dispersion and even papillary block glaucoma can result. If it lies against the anterior surface of the crystalline lens, cataract can result.

**Fig. 3.1.13** Endothelial Cell Loss 4 Years After Implantation of an Iris-Claw Lens in a 29-Year-Old Woman.

Long-term follow-up is needed for all types of phakic IOLs regarding endothelial cell loss (Fig. 3.1.13), glaucoma, iris abnormalities, and cataract formation.

### Add-on Intraocular Lenses in Pseudophakic Eyes

In contrast to obsolete “piggyback” procedures in which two IOLs were implanted in the capsular bag, the “add-on” concept involves placement of an additional IOL in the sulcus ciliaris after routine implantation of another lens into the capsular bag. The first “add-on” lens (HumanOptics, Germany) was first implanted in 2000. An add-on IOL can be performed immediately following cataract surgery in a single session or years later. Its indications include correction of residual ametropia after cataract surgery (spherical and/or cylindrical) and the treatment of pseudophakic presbyopia. This method avoids the risk and hazards of IOL explantation from the capsular bag. The exchangeability of the additional IOL may be advantageous in cases with expected change of refraction as in keratoplasty patients, in pediatric patients after cataract surgery, and for refractive power compensation in vitrectomized eyes filled with silicone oil.

### New or Alternative Approaches

#### Photorefractive Intrastromal Cross-Linking (PiXL)

Corneal collagen cross-linking, recently FDA approved to halt progressive ectatic disorders, uses UV light and a photosensitizer (riboflavin) to strengthen chemical bonds in the cornea. A mild flattening of the corneal

**Fig. 3.1.14 IntraStromal Rings.** Rings formed by femtosecond laser bubbles 6 months after IntraCor placement in the nondominant eye. The patient perceived the rings without upset.

zonules have been made taut by either scleral expansion or infrared laser application. However, this theory of accommodation is not supported by independent studies. The studies undertaken all support the classic accommodative mechanism described by Helmholtz.

### Axial Length

Presently, procedures that modify the axial length of the eye—by either resection of the sclera or reinforcement of the posterior pole in cases of high myopia—have a role in the management of staphyloma but not in the management of refractive error.

### Refractive Indexes

Although not intended to be a refractive procedure, the use of compounds with a different index of refraction during retinal surgery must be considered. In an aphakic eye, a convex bubble of silicone oil (with a higher index of refraction) will act as a positive IOL, rendering the eye more myopic while the oil stays in place. A gas bubble with a lower index of refraction will act as a diverging IOL, rendering the eye hyperopic while the gas stays in place.

## SUMMARY

Refractive surgery is an established subspecialty of ophthalmology with a rapidly growing choice of long-term proven and novel procedures. The responsible and caring refractive surgeon must choose the procedure that best fits the needs and expectations for each particular patient from among all the techniques described in Part 3 Refractive Surgery. The patient should be fully aware of all the risks and benefits as well as all the optical alternatives to the proposed procedure, especially if a novel procedure is recommended. Presbyopia correction is targeted with multiple approaches, but to date none is perfect.

### Definitions:

- Wavefront aberrometry is the measurement of the wavefront that emerges from an eye as a result of light reflecting from a focused light spot on the fovea. Application of Zernike polynomials allows characterization of a reconstructed estimated wavefront.
- Videokeratography is the computerized measurement of variation in curvature and dioptric power across the corneal surface that is typically based on the corneal reflection of the Placido pattern.
- Pachymetry is the measurement of corneal thickness.

### Key Features

- Preoperative evaluation for refractive surgery should involve documentation of refractive stability, review of both systemic and ophthalmic contraindications, manifest refraction, cycloplegic refraction, pupil measurements, pachymetry, wavefront analysis, corneal topography, slit-lamp examination, and dilated fundus examination.
- Care should be taken to identify patients at risk for postoperative corneal ectasia.
- Patient counseling is an important part of preoperative testing before refractive surgery.

## INTRODUCTION

Comprehensive preoperative evaluation of patients considering refractive surgery is often preceded by a brief screening examination to eliminate patients who are clearly not candidates for refractive surgery. Although it can help identify patients who would not benefit from refractive surgery, it also helps the surgeon plan the operative technique and further recommendations for a patient.

### General Considerations

#### Age

Laser corrective surgery is approved for those over 18 years of age who have had a stable refractive error over the previous 1–2 years. Although laser corrective surgery may be indicated in younger patients who are otherwise intolerant of traditional therapy, care must be taken because refractive error at this age often is unstable. A stable refractive error generally is defined as a  $\pm 0.5$  diopter (D) change in refraction over the past 1–2 years. Every patient presenting to a screening examination should be asked to discontinue all contact lens wear (1 week for soft nontoric lenses, 2 weeks for toric lenses, and at least 3 weeks for rigid lenses) and asked to bring their previous spectacles for assessment of refractive stability.

#### Degree of Correction

Although different laser platforms are approved for various thresholds of refractive correction, most surgeons opt to limit myopic correction to  $-10$  D and hyperopic and astigmatic correction to  $+4$  D to prevent postoperative corneal ectasia and haze and to avoid the unpredictability of correction at these higher refractions.

#### Patient Expectations

Perhaps the most important aspect of refractive surgery is appropriate counseling to set realistic expectations. Patients who are risk averse, who

### BOX 3.2.1 Systemic Contraindications to Photorefractive Keratectomy and Laser-in Situ Keratomileusis

#### Immunological Disease

- Autoimmune
- Collagen vascular
- Immunodeficiency

#### Pregnancy or Nursing (not absolute contraindication)

#### Abnormal Wound Healing

- Keloids (contraindicated for PRK only)
- Abnormal scars

#### Diabetes Mellitus (if corneal sensation is not intact)

#### Interference from Systemic Medications

- Isotretinoin
- Amiodarone hydrochloride

expect better vision than with glasses or contacts, or who have unrealistic expectations are likely not good candidates for refractive surgery. Appropriate counseling becomes even more important in patients between 40 and 50 years of age as presbyopia sets in and monovision may need to be a consideration. Another aspect to consider is a patient's occupation and hobbies. Those who perform activities that may put them at risk for flap dislocations should not be offered laser-assisted in situ keratomileusis (LASIK).

### Systemic Contraindications to Keratorefractive Surgery

A thorough medical history should be obtained from all patients considering refractive surgery. In particular, patients with a history of diabetes mellitus, pregnancy, autoimmune disease, collagen vascular disorders, thyroid disease, or abnormal wound healing may be at risk for poor outcomes postoperatively and should be identified before proceeding with surgery (Box 3.2.1).

#### Diabetes Mellitus

Uncontrolled diabetes not only leads to unstable refractions but also causes poor wound healing, persistent epithelial defects, and neurotrophic changes after laser surgery. A high risk of complications has been reported in the literature, including poor healing, worse refractive outcomes, and epithelial ingrowth.<sup>1,2</sup> Other studies did not show a significant complication rate in diabetes patients with well-controlled blood glucose.<sup>3,4</sup> Therefore it is recommended that refractive surgery be performed only in diabetes patients with tight blood glucose control ( $Hb A_{1c} < 7.9\%$ ) over the previous year, normal corneal sensation, and no signs of diabetic retinopathy.<sup>5</sup>

#### Pregnancy and Lactation

Refractive surgery during pregnancy is contraindicated because pregnancy can lead to transient changes in refractive error and cornea curvature and changes in tear quality. In addition, there are risks of fetal or infantile exposure to topical and systemic medications. There are multiple case reports of pregnancy-induced keratectasia following LASIK; it is important to counsel young female patients regarding this possibility.<sup>6–8</sup> Sharif reported a greater risk for corneal haze and myopic regression in women

who became pregnant within 5 months of photorefractive keratectomy (PRK). Starr also reported the case of a pregnant patient in whom overcorrection was induced and haze formation occurred.<sup>9,10</sup> It is recommended that patients wait 3 to 6 months after pregnancy and cessation of lactation before undergoing refractive surgery.

### Autoimmune Diseases

Uncontrolled collagen vascular disease is an absolute contraindication to undergoing laser refractive surgery, as it can lead to corneal melts and irregular healing. Patients with Sjögren's disease and thyroid-associated eye disease are predisposed to tear film irregularities and dry eyes.<sup>11</sup> Although most surgeons would agree that PRK will lead to poor healing in these patients, the debate is still ongoing whether patients with inactive or well-controlled collagen vascular disease can safely undergo LASIK.<sup>12</sup> Multiple studies have shown no additional complications with LASIK in patients with inactive disease and a normal ocular surface.<sup>3,13–15</sup> Case reports of severe complications also exist, however.<sup>11,16–19</sup> Appropriate counseling must be done in any patient with a collagen vascular disease interested in pursuing laser refractive surgery.

### Dermatological Keloid

Although dermatological keloid is listed as a precaution for LASIK and PRK, several studies have demonstrated good results without any additional complications after both PRK and LASIK.<sup>3,20,21</sup> Most surgeons at this point do not consider this a concern with laser surgery.

### Human Immunodeficiency Virus

A theoretical risk exists of transmission of human immunodeficiency virus (HIV) through laser plumes, but no reported cases have occurred to date that have shown such transmission. Nevertheless, adequate precautions must be taken while operating on patients with HIV. Hagen et al. used culture plates, and an excimer laser was used to ablate infected tissue.<sup>22</sup> None was culture positive. These patients also have a theoretical higher risk of infectious complications. Therefore only those on appropriate therapy and with adequate CD4 cell counts should be considered for refractive surgery.

### Medications

Multiple medications delay or inhibit wound healing after laser refractive surgery. Of these, amiodarone and isotretinoin need to be carefully considered before refractive surgery. Amiodarone is used to treat arrhythmias and can lead to multiple ocular side effects, including optic neuropathy, corneal and lenticular deposits, and halos around lights. Although there are reports of no increased complications, patients must be appropriately screened.<sup>23,24</sup> Isotretinoin is used to treat acne and can lead to dry eyes, blepharoconjunctivitis, and photosensitivity, all of which can complicate recovery.<sup>25</sup> Sumatriptan was previously considered to delay wound healing. However, recent reports do not show any significant adverse effects.<sup>26</sup> Various other systemic medications can exacerbate dry eye symptoms, and therefore patients on these should be appropriately counseled and treated.

## Ophthalmic Diseases

Multiple ophthalmic conditions necessitate special attention. Of note are disorders that lead to tear film deficiency, corneal dystrophies and ectasias, glaucoma, and other retinal and intraocular disorders (Table 3.2.1).

### Corneal Dystrophy

Any form of anterior corneal dystrophy is a contraindication for excimer laser use because this may lead to increased deposits.<sup>27</sup> Patients with epithelial basement membrane disease may benefit from PRK, as this can treat both the refractive error and the underlying pathology.<sup>28</sup> LASIK is contraindicated in patients with Fuchs' dystrophy because of the risk of corneal decompensation and potential for overestimation of corneal thickness in subclinical edema. There are case reports of safe performance of LASIK and PRK for posterior polymorphous corneal dystrophy.<sup>29,30</sup> Family history should be especially noted to ensure that any subtle changes of familial dystrophies are not missed.

### Corneal Curvature

Corneal curvature must be carefully examined because corneal ectasia after refractive surgery is a feared complication that can lead to severe loss of vision. Any signs or symptoms of corneal ectasia like keratoconus or pellucid marginal degeneration are a contraindication for laser refractive surgery. There are multiple criteria to evaluate and identify eyes at risk

TABLE 3.2.1 Ophthalmic Contraindications to Photorefractive Keratectomy

	Relative Contraindications	Absolute Contraindications
Ocular surface disease	Mild dry eye Lid disorders that affect the tear layer	Severe dry eye • Keratoconjunctivitis sicca • Exposure keratitis • Lid disorders that affect the tear layer Neurotrophic keratitis
Disorders that may be exacerbated by photorefractive keratectomy	Herpes zoster ophthalmicus/herpetic keratitis (if inactive for >1 year—unproved)	Herpes zoster ophthalmicus/herpetic keratitis (especially if active during the previous 6 months) Uncontrolled glaucoma
Abnormalities of corneal shape	Shape changes induced by contact lens Mild irregular astigmatism	Corneal ectasia • Keratoconus • Pellucid marginal degeneration • Keratoglobus High, irregular astigmatism
Other ophthalmic disorders	Posterior corneal dystrophies	Uveitis Diabetic retinopathy Progressive retinal disease

for postrefractive ectasias, but the key factors include abnormal topography, percent of tissue altered, thin corneal thickness, thin residual stromal bed, young age, and high myopia. Key elements of history such as rapidly changing refraction or a family history of ectasia can be helpful. Imaging using Placido-slit topography or Scheimpflug tomography can often identify suspicious changes in the anterior and posterior cornea.

### Ocular Surface Disease

Dry eyes are the most commonly experienced side effect after LASIK. Preoperative dry eye symptoms are at risk for worsening after laser surgery. It is important to optimize the ocular surface before refractive surgery. Although artificial tears are the mainstay of treatment, punctal plug placement during the LASIK procedure can decrease dry eye symptoms after LASIK.<sup>31</sup> Use of medications such as cyclosporine A after LASIK, while not significantly changing patient symptoms,<sup>32</sup> may improve refractive predictability.<sup>33</sup> Similarly, uncontrolled ocular allergy symptoms can lead to increased risk of perioperative complications; systemic treatment can decrease the risk of complications.

### Herpes Reactivation

Excimer laser treatment can lead to reactivation of herpes keratitis in both animal models and humans. Therefore refractive surgery was considered a contraindication. Recently however, de Rojas et al. presented a study in 48 patients who had inactive herpes keratitis for at least 1 year and in whom LASIK was performed while they were on oral and topical antiviral prophylaxis without any reactivation postoperatively.<sup>34</sup> The authors suggest careful patient selection, with inactive disease for at least 1 year, normal corneal sensitivities, and normal corneal parameters before proceeding. Given the risk of potentially devastating scarring if reactivation does occur, caution must be used while considering refractive surgery in this population.

### Glaucoma

Laser refractive surgery poses multiple complexities in patients with glaucoma. Although uncontrolled intraocular pressure is a contraindication for refractive surgery, patients with well-controlled glaucoma may be candidates. However, these patients often have ocular surface diseases that can complicate healing for LASIK or PRK. In addition, a change in corneal thickness can falsely change intraocular pressure measurements. Case reports exist of visual field, optic nerve, and nerve fiber layer changes occurring during the acute intraocular pressure elevation involved in LASIK flap creation,<sup>35,36</sup> and surface ablation procedures may be better suited in these patients. Another aspect to consider is the prolonged use of corticosteroids in patients undergoing PRK, which may lead to corticosteroid-induced intraocular pressure elevation, which occurs more commonly in patients predisposed to glaucoma.

### Other Considerations

Patients with visually significant or incipient cataracts must not undergo laser refractive surgery. Similarly, patients with significant retinal disease, latent strabismus, and monocular patients should not undergo laser refractive surgery.

**BOX 3.2.2 Ophthalmic Examination****Visual Acuity**

- Distance with and without correction
- Reading with and without correction

**Refraction**

- Current spectacle correction
- Manifest refraction
- Cycloplegic refraction with cyclopentolate 1%

**Topographical Analysis**

- Keratometry (measures central 3 mm)
- Computerized videokeratography

**Intraocular Pressure Measurement****External Examination**

- Ocular motility
- Ocular dominance
- Gross external examination measurements in bright and dim light

**Slit-Lamp Examination**

- Fluorescein stain
- Vital stain (if symptoms warrant)

**Dilated Funduscopy****Jones' Basal Tear Secretion Rate (if symptoms/signs warrant)****Pachymetry****OPHTHALMIC EXAMINATION**

The preoperative ophthalmic examination consists of determining patients' manifest and cycloplegic refraction, pupil diameter, ocular dominance, wavefront aberrometry measurement, corneal topography, pachymetry, slit-lamp examination, and dilated funduscopy (Box 3.2.2). Special care is required when manifest refraction is performed to avoid any errors. Cycloplegic refraction with 1% cyclopentolate is mandatory, especially in younger patients, to accurately measure refractive error in the absence of accommodation and to avoid myopic overcorrection.

A complete slit-lamp examination is important to identify problems with the lids, conjunctiva, cornea, or lens, which may lead to complications postoperatively. Eyelid malpositions, lagophthalmos, proptosis, and other external conditions that predispose the cornea to exposure must be recognized and treated before refractive surgery is attempted. Small interpalpebral fissures should be noted if LASIK is planned because of the difficulty in inserting the suction ring. Blepharitis and meibomian gland dysfunction should be treated aggressively before photoablation to reduce the risk of bacterial superinfection, to improve the quality of the tear film, and to prevent meibomian gland secretions and lash debris from becoming lodged in the interface between the flap and the corneal stroma.

Patients affected by significant corneal neovascularization extending within 1 mm of the ablation zone should be excluded from treatment. Extensive peripheral pannus should be noted and may be associated with bleeding following the keratectomy. Adequacy of the tear film should be assessed based on the Schirmer's test or tear meniscus height (approximately 0.3 mm) and tear-film breakup time ( $\geq 10$  sec).

An accurate preoperative measure of pupillary diameter in dim light should be obtained using an infrared pupillometer. Patients with scotopic pupil sizes  $\geq 6.5$  mm should be warned about the risks of night glare and halos following surgery, although the risk is lower with modern laser algorithms and blended ablation zones.<sup>37,38</sup>

In patients aged over 45 years, or those nearing the presbyopic age, a discussion regarding the postoperative need for reading glasses or the option for monovision correction should be discussed. Patients who are motivated to pursue monovision therapy should have ocular dominance assessed and should consider a trial of a monovision contact lens before surgery. Standard practice is to correct the dominant eye for distance and the nondominant eye for near sight in appropriate patients.

Keratometry should be measured to assess the power of the central cornea, to gauge the quality of the mires, and to provide a basis for later intraocular lens calculations. Tonometry, as part of a thorough examination, should also be obtained.

Dilated funduscopy should be performed to identify patients affected by progressive retinal disease, retinal holes, tears, or atypical lattice

degeneration, unrecognized diabetic retinopathy or myopic degeneration, and other pathologies that preclude photoablative treatment.

**ANCILLARY TESTING****Wavefront Measurement (Aberrometry)**

Recent advances in wavefront aberrometry have allowed for refined ablation profiles that correct for both higher- and lower-order aberrations in appropriate patients. Benefits to wavefront-guided LASIK include improved contrast sensitivity, reduced incidence of postoperative glare and halos, and reduced postoperative higher-order aberrations.<sup>39,40</sup> Wavefront testing should be the first examination performed before the eye is manipulated in any way. Any application of drops or tonometry can alter the results and thus should be avoided before testing. While waiting, patients should avoid reading magazines or other materials in the waiting room to minimize accommodation and dessication of the ocular surface. In all cases, wavefront measurements should be compared with the manifest and cycloplegic refractions to confirm consistency. Higher-order aberration indices, such as vertical coma, should be further reviewed for evidence suggestive of subclinical keratoconus.<sup>41</sup>

**Computerized Videokeratography**

Computerized videokeratography is crucial in the preoperative evaluation of patients for refractive surgery. Postoperative ectasia remains the most feared complication of photorefractive surgery; appropriate screening with corneal topography is absolutely essential. In any preoperative evaluation for refractive surgery, one must maintain a high degree of suspicion for ectatic disorders.

Care should be taken to establish the stability of patient corneal topography before surgery. Progressive changes in corneal topography may be indicative of ectatic disease or corneal molding (warping) due to rigid or soft contact lens wear. Because distortion from long-term contact lens wear may persist for a long time, patients should discontinue all contact lens wear before the preoperative examination. Prolonged contact lens cessation is warranted in patients who demonstrate poor stabilization of their corneal topography.<sup>42,43</sup>

**Pachymetry**

Pachymetry must be performed in all patients before LASIK. It is mandatory that the postablation corneal bed following LASIK be at least 250  $\mu$ m in thickness to avoid iatrogenic corneal ectasia and refractive instability. Residual bed thickness can be estimated from the baseline corneal pachymetry, the anticipated flap thickness, and the expected depth of ablation.

**Counseling**

Not all patients who meet medical and ophthalmic criteria for refractive surgery are necessarily good candidates for the procedure. Patients with unrealistic expectations are likely to be dissatisfied after surgery. Appropriate counseling regarding the risks of over- or undercorrection, postoperative dry eye, or postoperative glare and halos should be performed routinely. Patients should be informed of the potential need for spectacles after surgery for certain tasks such as driving at night. High hyperopes should be made aware of the decreased predictability of photoablative treatments in hyperopic cases. Presbyopic myopes should be made aware that the removal of distance glasses to achieve better near vision would no longer be possible after refractive surgery.

The preoperative evaluation of the patient for refractive surgery is lengthy and must be performed in an unrushed manner. However, it is time well spent because the best treatment for complications and disappointment is avoidance.

# Excimer Laser Surface Ablation: Photorefractive Keratectomy (PRK), Laser Subepithelial Keratomileusis (LASEK), and Epi-LASIK

## 3.3

Sandeep Jain, David R. Hardten, Leonard P.K. Ang, Dimitri T. Azar

### Definitions:

- Photorefractive keratectomy (PRK) is a procedure in which the cornea is reshaped using an excimer laser. PRK involves epithelial removal and photoablation of Bowman's layer and anterior corneal stromal tissue. In contrast to laser-assisted in situ keratomileusis (LASIK), there is no need for flap creation with a microkeratome.
- Laser subepithelial keratomileusis (LASEK) and epi-LASIK are corneal surface ablative refractive procedures.
- LASEK involves creating an epithelial flap with dilute alcohol and repositioning this flap after laser ablation.
- Epi-LASIK involves the use of a motorized epithelial separator to mechanically separate the corneal epithelium from the stroma.

### Key Features

- Excimer laser surface ablation results in removal of a precise amount of tissue from the anterior cornea. The central cornea is reprofiled to achieve myopic, hyperopic, or astigmatic correction.
- The refractive result is related to the depth of ablation and the diameter of the optical zone.
- Preoperative assessment plays a key role in determining a safe and effective outcome. It includes corneal pachymetry, topography, and cycloplegic refraction.
- Mitomycin-C is useful to prevent corneal haze and scarring in high myopic corrections.
- Wavefront guided ablations result in higher percentage of patients achieving uncorrected visual acuity of 20/20 or better compared with conventional ablations.
- PRK, LASEK and epi-LASIK are considered in patients with thin, steep, or flat corneas and in patients predisposed to flap trauma in thinner corneas, where creation of LASIK flap may leave less tissue than desired (usually 250  $\mu\text{m}$  of corneal tissue) remaining to the posterior stroma.
- Postoperative complications of PRK, LASEK, and epi-LASIK include epithelial healing, pain, infiltrates and infection, dry eye, and corneal haze.
- LASEK-related intraoperative complications include alcohol leakage, incomplete epithelial detachment, and laser-related complications.
- Epi-LASIK-related intraoperative complications include flap-related complications (when these occur the procedure may be converted to PRK) and laser-related complications.

### INTRODUCTION

The surgical treatment of myopia, hyperopia, and astigmatism has made great strides over time, with the introduction and advancement of the excimer laser PRK followed by LASIK surgery. Ultraviolet radiation at 193 nm wavelength utilized by the excimer laser can remove precise amounts of tissue from the anterior cornea. Use of the excimer laser for the treatment of myopia, hyperopia, and astigmatism is now well established.<sup>1-7</sup>

Other corneal surface ablative procedures include laser-assisted subepithelial keratomileusis (LASEK) and epi-LASIK. In principle, they combine the advantages of both LASIK (laser-assisted in situ keratomileusis) and PRK, while at the same time overcoming some of their problems.<sup>8-18</sup> LASEK was first conceived independently in 1996 by Azar,<sup>9</sup> as well as Cimberle and Camellin.<sup>10</sup> LASEK involves creating an epithelial flap with dilute alcohol solution and repositioning this flap after laser ablation, thus eliminating any inherent flap complications. Epi-LASIK makes use of a motorized epithelial separator to mechanically separate the corneal epithelium in toto from the stroma without the use of alcohol or chemicals.<sup>14,15</sup> This device makes use of a proprietary oscillating blade that separates the epithelial layer at the layer of Bowman's membrane without dissecting the corneal stroma.

Development of excimer lasers began in 1975 when Velasco and Setser<sup>19</sup> noted that metastable rare gas atoms such as xenon (Xe) could react under high pressures with halogens such as fluorine (F) to produce unstable compounds such as XeF.<sup>20</sup> These compounds rapidly dissociated to the ground state of the individual molecules associated with the release of an energetic ultraviolet photon and could be made to undergo light amplification by stimulated emission when they were excited by an electron beam, with the argon-fluorine (ArF) molecule emitting light with a wavelength of 193 nm.<sup>21</sup> The ablation thresholds, ablation rates, and healing patterns for different excimer wavelengths were described by Krueger and Trokel.<sup>22-24</sup> The ablation threshold for the cornea is the fluence at which tissue removal begins, which is approximately 50 mJ/cm<sup>2</sup> for 193 nm. The 193 nm light has very low tissue penetrance, enabling the laser to operate on the surface of the corneal tissue with precision and safety.

Large-area ablation with resculpting of the cornea to correct refractive errors is termed *laser keratomileusis*. Tissue is removed with great precision, and the corneal epithelium heals over the ablated area to create a smooth surface. About 0.24  $\mu\text{m}$  of tissue is removed with each laser pulse. Corneal epithelium ablates at a slightly faster and more irregular rate than corneal stroma, which is the reason that the epithelium is typically removed mechanically before ablation of the stroma for the PRK procedure. Bowman's layer ablates about 30% slower than the stroma, and fluorescein decreases the ablation rate by about 40%.

### ABLATION PROFILES

Munnerlyn<sup>25</sup> described the direct relation between the amount of tissue that must be removed to produce a certain refractive result and the optical zone size. The relationship can be simplified to:

$$\text{Depth of ablation } (\mu\text{m}) = [\text{diameter of optical zone (mm)}]^2 \times 1/3 \text{ power (D)}$$

As the optical zone is increased, the ablation depth needs to be increased. The optical zone size and depth are optimized to reduce excessive wound healing seen in deep ablations and the excessive halos, edge glare, and irregular astigmatism seen with small optical zones.<sup>26</sup>

In correction of spherical hyperopia, the cornea needs to be reshaped into a steeper convex structure. This can be achieved by a peripheral annular ablation with peripheral flattening creating central corneal

steepening. Generally, a larger (9–9.5 mm) ablation diameter is required to achieve permanent steepening of the cornea. It is more challenging to deliver larger-diameter hyperopic ablations than the equivalent myopic correction.

Excimer laser surgical correction of astigmatism requires that the cornea be ablated in a cylindrical or toric pattern. In the early excimer systems, the excimer laser beams were passed through a set of parallel blades that gradually open as directed by the computer algorithm. The orientation and speed of opening depends on the orientation and amount of astigmatism to be corrected. Flattening occurs perpendicular to the long axis of the slits. No change in power occurs along the axis of the slits. Another method of creating a toric ablation utilizes an ablatable mask. The laser first ablates the thinnest areas of the mask, thus allowing greater treatment of the cornea in areas where the mask is thinnest.<sup>27</sup> Any pattern can be created by differential protection of the cornea from treatment.

A computer-controlled scanning beam can be utilized to treat astigmatism. The size of the beam can be varied to create a transition zone, preventing a steep step off at the edges of treatment. With this method, it is possible to steepen, rather than flatten an axis, thus allowing for a more direct and tissue-conserving treatment of hyperopic astigmatism. Wavefront-guided customized corneal ablation profiles have been introduced for correction of irregular astigmatism (higher-order aberrations) as well as spherocylindrical refractive errors.

## INDICATIONS

PRK, LASEK, and epi-LASIK surface ablation may be performed in patients who are at low risk for subepithelial haze with low to moderate myopia and myopic astigmatism. The ideal candidates for LASEK and epi-LASIK are those with mild to moderate myopia up to −700 diopters (D).<sup>12,17</sup> LASEK has also been shown to be effective for hyperopia up to +4.00 D.<sup>28</sup>

Surgeons should consider these surface ablative refractive procedures for patients whose corneal characteristics render them at greater risk for LASIK, such as those with thin corneas where less than 250  $\mu\text{m}$  of residual stromal bed would be left and those with steep or flat corneas. These would also be the preferred surgical procedures in patients with lifestyles or professions that predispose them to flap trauma. LASEK may also be a better choice for patients with narrow palpebral fissures where the microkeratome cannot be well applied.

Contraindications for these procedures include exposure keratopathy, neuropathic keratopathy, severe dry eye (Sjögren's syndrome), keratoconus, central or paracentral corneal scars, unstable myopia, and irregular astigmatism.<sup>11,12</sup>

## PREOPERATIVE EVALUATION

As for any refractive procedure, the preoperative workup for PRK, LASEK, and epi-LASIK includes uncorrected and best-corrected distance and near visual acuities with a manifest and cycloplegic refraction. Ocular dominance testing, anterior segment and posterior segment examinations, keratometry, tonometry, pachymetry, aberrometry, and computerized topographical analysis are other important parts. A careful systemic and ocular history and examination is necessary to look for conditions that may require preoperative management or contraindicate the procedure (Box 3.3.1). For example, mild degrees of dysfunctional tear syndrome or dry eye (Fig. 3.3.1) can be managed preoperatively with lid hygiene, artificial tears, and topical cyclosporin for better early postoperative recovery. Meticulous preoperative counseling is also a very important aspect, as for any refractive procedure.

## PRK SURGICAL TECHNIQUE

### Patient Preparation and Epithelial Removal

The initial patient preparation is similar to all the three surface ablation procedures. The patient is positioned under the microscope, and the head is carefully aligned to make sure that the iris plane is perpendicular to the laser beam. After topical anesthesia (0.5% proparacaine or tetracaine), the eyelids and periocular skin are prepped with dilute povidone–iodine (Beta-dine) solution. A lid speculum is placed to provide adequate exposure of the globe. Careful centration with the eye aligned in the x-, y-, and z-planes is crucial.

It is important to perform the treatment as soon as possible after the proparacaine or tetracaine drops are instilled or have the patient close their eyes to prevent exposure keratitis from poor blinking. Drying of the

### BOX 3.3.1 Indications and Cautions

#### Potential Preference of PRK Over LASIK

- Thin corneal pachymetry
- Epithelial irregularities/dystrophies
- LASIK complications in the contralateral eye
- Predisposition to trauma
- Low myopia
- Irregular astigmatism
- Dry eyes

#### Cautions

- Postoperative pain intolerance/concern
- Keratoconus
- Glaucoma
- Pregnancy
- Advanced diabetes
- Collagen vascular disease
- Previous herpes (simplex or zoster) infection
- Severe dry eye
- Untreated blepharitis
- Neurotrophic cornea
- Peripheral ulcerative keratitis
- Patients on isotretinoin (Accutane), amiodarone (Cordarone), or sumatriptan (Imitrex)

inferior half of the cornea, as often occurs after anesthetic drops have been instilled, can lead to increased thinning inferiorly.

The epithelium is marked with a 7- or 8-mm optical zone marker centered on the pupil for myopia or a 9- or 10-mm marker for hyperopia or wavefront correction. It is helpful to remove a 1-mm larger area of epithelium than the planned ablation. Mechanical epithelial removal involves the use of a Tooke knife, disposable excimer spatula, or rotating brush. Alternatively, alcohol (18%–25% ethanol for 21–30 seconds) can be used to loosen the epithelium or excimer laser for partial or complete removal. The laser is typically set to a depth of approximately 45  $\mu\text{m}$ , and the epithelium being ablated by the laser beam can be visualized under blue fluorescence. The ablation is stopped when a change from a fluorescent pattern to a dark pattern is seen, indicating that the epithelium has been ablated. If fluorescence persists across the whole area after a 50  $\mu\text{m}$  ablation has been performed, an additional depth of 25  $\mu\text{m}$  should be set for the laser. It may be helpful to scrape the remaining epithelium. It is important to remove the epithelium totally. Any residual epithelium will create an uneven ablation and irregular astigmatism. Also, epithelial removal should be quick to avoid corneal hydration changes.

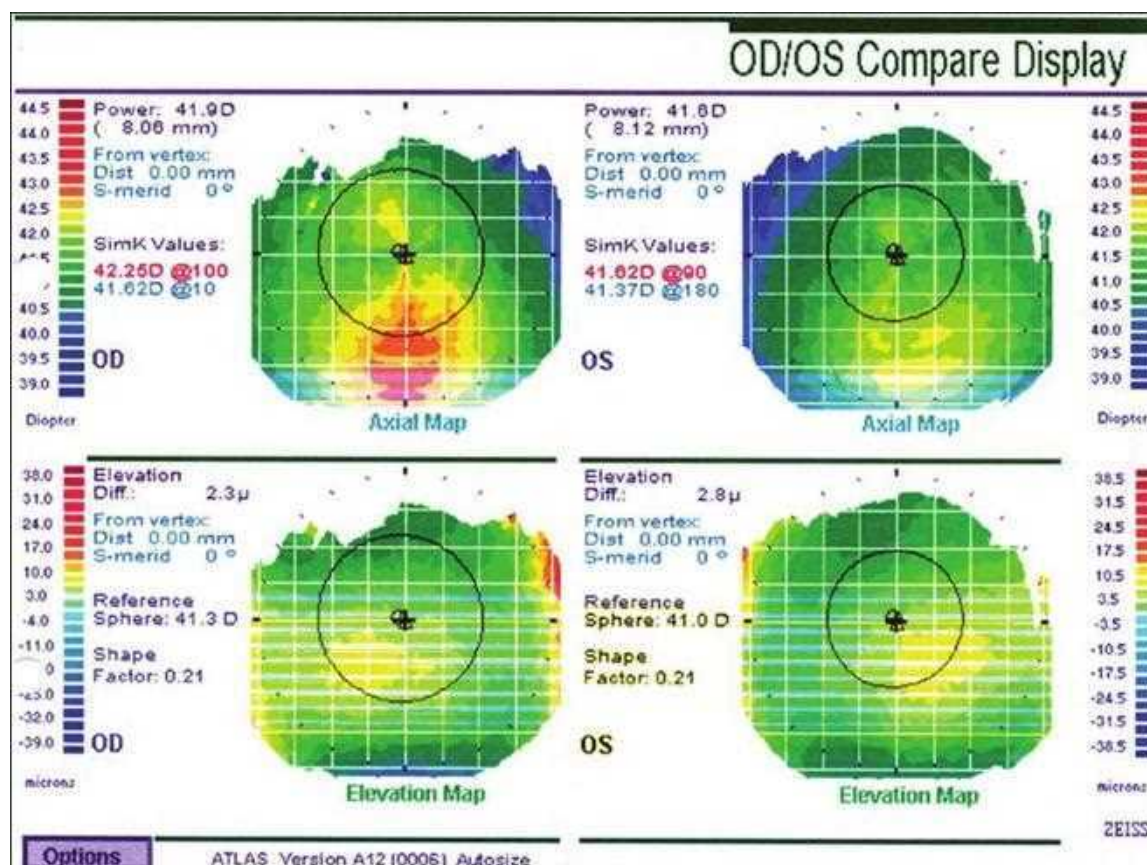

### Stromal Ablation

The ablation should promptly follow epithelial removal to prevent drying, which can lead to increased haze and scarring.<sup>29–30</sup>

Centration is rechecked after epithelial removal. For astigmatic corrections, alignment on the proper axis should be verified by marking the patient's limbus at the 12 and 6 o'clock positions with gentian violet dye on a Sinskey hook at the slit lamp before the procedure. The ultraviolet excimer lasers used have wavelengths outside the visible spectrum; an auxiliary aiming device that is coaxial to the ablating laser is required to make certain the laser is centered on the eye. Helium–neon lasers, laser diodes, or a coaxial aiming target are commonly used for this. In automated systems with eye trackers, this is used only for initial alignment, but in manually controlled systems, it is used to align the eye during the entire procedure.

The ablation is begun, centered over the pupil with the patient looking at the fixation light. Eye movements should be minimized during the ablation to reduce irregular surfaces. The use of an eye tracker is helpful in maintaining centration.<sup>31–32</sup> It is important to make certain that the hydration status of the corneal stroma is uniform during the procedure. If excess fluid is detected, the procedure should be paused and the excess fluid removed by using a cellulose sponge to dry the cornea (Fig. 3.3.2). Likewise, if the cornea becomes too dry, a cellulose sponge can be used to evenly hydrate it. Inadequate or excessive tissue hydration leads to more or less tissue ablation per pulse, resulting in an overcorrection or undercorrection, respectively.

**Fig. 3.3.1 Inferior Steepening and Irregularity of the Topography Is Seen in This Young Patient With Dry Eye and Blepharitis.** This patient improved significantly with lid hygiene, artificial tears, and topical cyclosporin 0.05% for 1 month.

**Fig. 3.3.2 A Merocel Sponge Can Be Used to Remove Excess Moisture in a Uniform Fashion.** Maintaining proper central corneal hydration may improve results.

the cornea while the barrel of the marker is filled with two drops of 18% ethanol. After 25–35 seconds, the ethanol is absorbed using an aspiration hole followed by dry sponges (Weck-cel or Merocel, Xomed, Jacksonville, FL), to prevent alcohol spillage onto the epithelium outside the marker barrel. The ethanol application may be repeated for an additional 10–15 seconds.

One arm of a modified curved Vannas scissors or a jeweler's forceps is inserted under the epithelium and traced around the delineated margin of the epithelium, leaving 2–3 clock hours of intact margin, preferably at the 12 o'clock position. The loosened epithelium is peeled as a single sheet using a jeweler's forceps, spatula, or a Merocel sponge, leaving a flap of epithelium with the hinge still attached. The ablation is then initiated immediately using an excimer laser.

After ablation, a 30-gauge anterior chamber cannula is used to hydrate the stroma and epithelial sheet with balanced salt solution. The epithelial sheet is replaced on the stroma using the straight part of the cannula under intermittent irrigation. The epithelial flaps are realigned using the previous marks. The flap is then allowed to dry for 2–5 minutes.

A bandage contact lens is placed on the operated eye at the end of the procedure.

### Epi-LASIK Surgical Technique (Fig. 3.3.4)

The corneal epithelium is dried with sponges after proper positioning and ocular surface irrigation with balanced salt solution using an anterior chamber cannula. The cornea is marked with a standard LASIK marker.

The subepithelial separator is applied to the eye and suction is activated by a foot pedal. The oscillating blade separates the epithelium leaving a 2–3-mm nasal hinge, the suction is released, and the device is removed from the eye. The epithelial sheet is reflected nasally using a moistened Merocel sponge or a spatula. Laser ablation is then initiated immediately, with use of an excimer laser. The cornea is then irrigated with balanced salt solution. The epithelial sheet is carefully repositioned using the straight part of the cannula. The replaced corneal epithelial sheet is left to dry for 2–3 minutes to allow adhesion to the underlying corneal stroma. Some surgeons may choose to discard the epithelial flap instead. In this situation, the subepithelial separator would then simply remove the epithelium before the laser ablation.

At the end of the procedure, a bandage contact lens is placed on the operated eye.

### LASEK Surgical Technique (see Fig. 3.3.3)

Patient is prepared and eye aligned as described earlier. Just before surgery, topical broad-spectrum antibiotics (e.g., tobramycin or a fluoroquinolone) may be applied prophylactically. Some surgeons use topical nonsteroidal anti-inflammatory drugs (NSAIDs) for pain relief. Dilute ethanol at a concentration of 18% is prepared by drawing 2 mL of dehydrated alcohol into a 12 mL syringe and diluting it with sterile water to 11 mL.<sup>9,12</sup>

The cornea is marked with 3-mm circles around the corneal periphery to allow the surgeon to have the precise reference points to realign the flap over the corneal bed. An alcohol dispenser consisting of a customized 7- or 9-mm semisharp marker (ASICO, Westmont, IL) attached to a hollow metal handle serves as a reservoir for the 18% alcohol.

Firm pressure is exerted on the central cornea and a button is pushed on the side of the handle, releasing the alcohol into the well of the marker. Alternatively, a 7-mm optical marker (Storz, St Louis, MO) is used to delineate the area centered on the pupil. Gentle pressure is applied on

**Fig. 3.3.3 Our Current LASEK Technique.** (A) Multiple marks are applied around the corneal periphery, simulating a floral pattern. (B) An alcohol dispenser consisting of a customized 7- or 9-mm semisharp marker attached to a hollow metal handle serves as a reservoir for 18% alcohol. Firm pressure is exerted on the cornea, and alcohol is released into the well of the marker. (C) After 25–30 seconds, the ethanol is absorbed using a dry cellulose sponge. (D) One arm of a modified Vannas scissors (note knob at tip of lower arm) is then inserted under the epithelium and traced around the delineated margin of the epithelium, leaving a hinge of 2–3 clock hours of intact margin, preferably at the 12 o'clock position. (E) The loosened epithelium is peeled as a single sheet using a Merocel sponge or the edge of a jeweler's forceps, leaving it attached at its hinge. (F) After laser ablation is performed, an anterior chamber cannula is used to hydrate the stroma and epithelial flap with balanced salt solution. (G) The epithelial flap is replaced on the stroma using the cannula under intermittent irrigation. (H) Care is taken to realign the epithelial flap using the previous marks and to avoid epithelial defects. The flap is allowed to dry for 2–5 min. Topical corticosteroids and antibiotic medications are applied. (I) A bandage contact lens is placed. (Reproduced from Azar DT, Taneri S. LASEK. In: Azar DT, Gatinel D, Hoang-Xuan T, editors. *Refractive surgery*. 2nd ed. Philadelphia: Elsevier; 2007. p. 239–47.)

### Surface Ablation With Mitomycin-C

In refractive surgery, patients with high myopia are at a higher risk of haze formation.<sup>4,33–35</sup> Early haze formation has been more common with higher attempted corrections, smaller ablation zones (<4.5 mm), male gender, ablations deeper than 80  $\mu$ m, and discontinuation of topical corticosteroids.<sup>36–37</sup> Subepithelial stromal tissue reformation following photorefractive ablation is attributable to abnormal activation or proliferation of stromal keratocytes following surgical trauma to Bowman's layer.<sup>38–39</sup>

Mitomycin-C (MMC) is an alkylating antibiotic substance with anti-proliferative and antifibrotic actions. Topical MMC 0.02% (0.2 mg/mL)

application for 2 minutes on the exposed stromal bed has been used successfully to treat central subepithelial fibrosis after radial keratotomy (RK) or PRK.<sup>40–42</sup> It also has a role in prevention of corneal haze formation after PRK for treatment of myopia and hyperopia.<sup>43</sup> The typical application times range between 1 and 2 minutes, although as little as a 12-second application of 0.02% MMC has been found effective for prevention of corneal haze.<sup>44</sup> Application is performed immediately after the laser ablation. The corneal surface and the entire conjunctiva are then vigorously irrigated with 20 mL of cold normal saline to remove any residual MMC.

PRK with MMC application may offer a good alternative for patients with high refractive error, where the cornea is not thick enough for a safe

**Fig. 3.3.4 The Epi-LASIK Technique.** (A) Marks are applied around the corneal periphery. (B,C) The epikeratome is applied to the eye with suction; the oscillating blade separates the epithelium. Once the separator reaches its final position, suction is released and the device is removed from the eye. (D) With the use of either a moistened Meroel sponge or a metallic spatula, the epithelium is reflected to reveal the corneal stroma. (E) Laser ablation is performed. (F,G) The cornea is irrigated with balanced salt solution and the epithelial sheet is carefully repositioned. (H,I) The replaced corneal epithelial sheet is left to dry for 2–3 minutes, and a bandage contact lens is placed. (Reproduced with permission from Azar DT, editor, Ghanem RC, DVD editor. Refractive surgery. 2nd ed. St Louis: Mosby Elsevier; 2006.)

LASIK procedure or if LASIK is contraindicated for other reasons. It has also been tried in post keratoplasty, post RK, and immediately after the occurrence of the LASIK flap buttonhole with successful results.<sup>45–47</sup>

### Wavefront-Guided Surface Ablation

Conventional laser treatments tend to increase the higher-order aberrations (HOA) in an attempt to treat the lower-order aberrations by altering the corneal shape from its normal prolate to a more oblate configuration. Spherical aberration is the most common of these, causing mainly loss of contrast sensitivity rather than Snellen visual acuity.<sup>48</sup> Wavefront-guided laser utilizes the preoperative wavefront of the patient and compares it to the desired postoperative wavefront. The difference is used to generate a three-dimensional map of the planned ablation. Thus customized,

computer-generated, complex patterns of ablation are delivered in an attempt to decrease the pre-existing HOA as well.

## RESULTS

### Photorefractive Keratectomy for Myopia and Astigmatism

Outcomes have improved over time as techniques and lasers have evolved based on the experience gained from early studies. Treatments limited to low myopia (less than  $-6.00$  D) have achieved a final mean spherical equivalent refraction between  $-0.04$  D and  $-0.44$  D postoperatively. Over various studies, 25.9%–80% of patients have achieved a postoperative

uncorrected visual acuity (UCVA) of 20/20 or greater, whereas about 82%–91.5% of patients received a best-corrected visual acuity (BCVA) of 20/40 or greater. Loss of BCVA, a measure of safety, is typically 2%–4% but rises significantly in studies treating high and very high myopia.<sup>13,49–53</sup>

The numbers for high myopia fall to about 27%–30% of patients achieving 20/40 or better vision for more than –10.00 D of myopia, with 39% of these within 1.00 D of emmetropia.<sup>34,54</sup> Another study reported 42.9% of eyes within 1.00 D of intended correction 6–9 years after PRK for myopia  $\geq 6.00$  D.<sup>55</sup>

From the 1.5- and 6-year follow-up studies it was reported that all myopic PRK ablations were accompanied by a hyperopic shift that increased with the magnitude of myopic correction followed by a period of regression that compensated for the hyperopic shift, finally stabilizing in 3–6 months. The standard deviation of the postoperative endpoint increased with an increase in attempted correction. No significant regression occurred after 1.5 or after 6 years.<sup>2,56–57</sup> Refractive stability, in fact, continues for up to 12 years, as reported by Rajan et al.<sup>58</sup>

It has been shown that refractive results in flap-based and PRK-based procedures are comparable in mild-to-moderate myopia patients but are better in high-myopia patients.<sup>59</sup> Visual rehabilitation after PRK is slower than after LASIK. A recent report comparing the two procedures showed similar visual acuity efficacy in the treatment of eyes with high myopia ( $\geq -10.00$  D) in the long term, with LASIK having superior efficacy and safety over PRK within the first 2 years after surgery.<sup>60</sup>

Astigmatism correction is more complicated than myopia or hyperopia correction because it involves both the amount and the orientation of the astigmatism. More recent trials have shown promising results in treating astigmatism. In general, results in those with low and moderate levels of astigmatism have greater predictability and safety than those with high astigmatism. PRK for the correction of mixed astigmatism is a useful technique in terms of efficacy, safety, and predictability with conventional as well as customized ablation techniques.<sup>61</sup>

## Photorefractive Keratectomy for Hyperopia

The treatment of hyperopia with excimer laser PRK has lagged behind that of myopia. Reproducible steepening of the cornea has been more difficult to obtain than flattening, and regression has been more of a problem.

Hyperopic PRK shows good predictability and safety in those with low and moderate hyperopia; results for high hyperopes are less impressive. In a study by Pacella et al.,<sup>59</sup> including hyperopia up to +4.75 D, 100% of patients achieved 20/30 acuity or better and the mean postoperative spherical equivalent was –0.01 D. In contrast, for patients with between +11.00 and +16.00 D of hyperopia, only 37% had a spherical equivalent within 1 D of emmetropia.<sup>62</sup>

The long-term efficacy and stability of spherical and astigmatic PRK have been found to be similar to LASIK.<sup>63</sup> Nevertheless, the epithelial healing time was predictably longer for the PRK group. Eyes that underwent LASIK experienced less pain/discomfort and faster visual recovery. Mitomycin-C has been shown to prevent haze formation and improve predictability and efficacy of PRK.<sup>64</sup>

## Wavefront-Guided PRK

Custom PRK has been shown to be safe and effective for the correction of low to moderate and high myopia, compound myopic astigmatism, and hyperopia. In a recent study, the mean refractive spherical equivalent was  $-0.16 \pm 0.45$  1 year after custom myopic PRK, with 96.6% of eyes within  $\pm 1.00$  D of intended correction. In another study, 80% of eyes achieved uncorrected distance visual acuity (UDVA) of 20/20.<sup>65–67</sup> A randomized, prospective, contralateral eye study comparing custom and conventional PRK showed that the mean uncorrected and corrected visual acuity did not differ significantly in the two groups. Higher order aberration was less in the custom group, but this did not seem to correlate with clinical outcomes.<sup>68</sup> We must realize that it is not possible to totally eliminate these HOA with wavefront treatment either.<sup>69</sup>

Compared with wavefront-guided LASIK, wavefront-guided PRK had similar efficacy, predictability, safety, and contrast sensitivity. In one study, wavefront-guided PRK induced statistically fewer HOA than wavefront-guided LASIK.<sup>53,66,70</sup> Wavefront-guided PRK with MMC has been used to successfully treat residual myopia/hyperopia in eyes with prior RK, with a mean improvement of three lines of uncorrected acuity in both the groups.<sup>71</sup>

## COMPLICATIONS

### General Complications for All Surface Ablation Procedures

#### *Undercorrection or Overcorrection*

Corneal wound healing response after surface ablation is more complex than after LASIK for the same amount of correction.<sup>72</sup> Therefore complications such as regression, overcorrection, and haze are more common. Refractive regression is a manifestation of postoperative stromal keratocyte healing or, less importantly, epithelial hyperplasia. Excessive fluid or desiccation of the corneal stroma intraoperatively can result in an undercorrection or overcorrection.

In cases of undercorrection with residual myopia, the simplest form of management is to use spectacles or contact lenses. Contact lens use can be highly successful after surface ablation. An attempt can be made to reduce wound healing in patients with mild undercorrection by using corticosteroids; mixed results have been reported with this technique. Residual myopia also can be managed by further refractive surgery, including additional PRK or LASIK.

Overcorrection is a desired result in the first few months after surface ablation, as there is usually regression of 5%–10%. If the patient has a greater degree of overcorrection than is expected at 1 month or longer after surgery, an attempt may be made to increase wound healing by tapering the corticosteroids rapidly. If additional stromal remodeling occurs during this corticosteroid taper, a decrease in the amount of hyperopia will occur. A rapid taper of corticosteroids may induce corneal haze in some patients, so monitoring is important. Also, as previously mentioned, refractive modulation with corticosteroid therapy is not always successful.

#### *Epithelial Problems*

Hyperopic ablation is limited by the large epithelial defect created. Normally, the defect heals in 3–4 days. Inadequate healing can lead to persistent epithelial defects. Pre-existing dry eye, autoimmune connective tissue disease, or diabetes mellitus predispose to it. Medication toxicity can lead to superficial punctate keratitis (SPK). Discontinuation of such medication can be considered along with use of preservative-free artificial tears. Persistent defects need to be treated aggressively with pressure patching, autologous serum, punctual occlusion, or cyclosporine as per the individual case. This is necessary to avoid corneal haze, scarring, and a possible risk of infection.

#### *Corneal Haze/Scar Formation*

Transient haze after surface ablation, which can be visually significant and can cause loss of BCVA (Fig. 3.3.5), may result from the corneal wound-healing process. The haze formation can be visually significant and cause loss of BCVA (see Fig. 3.3.5). In most cases, it appears within a few weeks as a mild, diffuse, whitish anterior stromal opacity, which increases in severity for 2–4 months and then fades. Late-onset haze is defined as haze presenting 4–14 months postoperatively.<sup>73</sup> It has been linked to ultraviolet exposure; patients should be cautioned to always wear ultraviolet protection when outdoors for the first few years following the procedure. Corneal scar development may be prevented by the prophylactic use of mitomycin-C 0.02% in patients with higher spherical equivalent corrections.<sup>44</sup> Surgical removal of the scar with the excimer laser can improve visual function in these patients.

#### *Dry Eyes*

Dry eye symptoms are thought to be less common following surface ablation procedures compared with LASIK. The reinnervation process is speedier after these, because the ablated nerve endings are located close to the epithelial surface.<sup>74</sup>

#### *Infectious Keratitis*

Although rare, infectious keratitis can be a devastating complication of any refractive surgery. The breakdown of the corneal epithelium as a barrier and the use of an extended wear bandage contact lens are predisposing factors for development of corneal infection. In addition, the use of topical corticosteroids may suppress the immune response to infection. Staphylococcus species have been noted as the most common causative organisms and streptococcus species as the next, with *Pseudomonas aeruginosa* also causing bacterial keratitis.<sup>75</sup> Opportunistic organisms such as *Mycobacterium chelonae* and fungal infections have been reported. Prophylactic broad-spectrum antibiotics such as fourth-generation fluoroquinolones

**Fig. 3.3.5 Corneal Haze After PRK in a Patient With Prior LASIK When No Mitomycin-C Was Used.** (A) Slit beam of subepithelial haze. (B) Haze evident over area of photoablation.

currently are the most commonly prescribed to try to reduce the potential for infection in the postoperative period.

## Specific Intraoperative Complications Related to LASEK

### *Alcohol Leakage During Surgery*

Alcohol leakage may occur during LASEK and spill over to the limbal and conjunctival epithelium. When this happens, it should be immediately absorbed with a sponge and the area irrigated thoroughly with balanced salt solution. No significant long-term complications are likely to occur if prompt irrigation is performed.

### *Incomplete Epithelial Detachment*

Insufficient alcohol exposure and poor surgical technique may lead to incomplete epithelial detachment. This may in turn result in tearing of the flap, fragmentation, or creating a buttonhole. If epithelial detachment is difficult, additional application of alcohol usually is sufficient to facilitate complete detachment of the epithelial sheet. If this still fails, then the

remaining epithelium may be scraped off and the procedure easily converted to PRK.

## Specific Intraoperative Complications Related to Epi-LASIK

The major difference between LASEK and epi-LASIK is that the separation of the epithelial sheet is performed mechanically without exposing the cornea to alcohol or other chemical agents that may be toxic to the epithelial cells.<sup>76,77</sup> The use of a motorized epithelial separator, however, creates a different set of flap-related problems, such as a free or incomplete epithelial flap and tearing, fragmentation, or buttonhole of the flap. However, unlike the flap-related complications of LASIK, when these occur in epi-LASIK, the residual epithelium may be removed mechanically and the procedure easily converted to a standard PRK with equally good results. This is where epi-LASIK offers advantages over LASIK, where the corneal flap-related complications often require that the LASIK procedure be abandoned.

## CONCLUSIONS

The excimer laser surface ablation procedures include PRK, LASEK, and epi-LASIK. The techniques are still developing, and there will certainly be significant advances in the future. Developments of customized corneal ablation using wavefront analysis, laser registration systems, and use of mitomycin-C have been the most recent significant achievements to date in laser vision correction. Although LASIK continues to be the preferred surgical procedure in most situations, PRK, LASEK, and epi-LASIK are useful alternatives in patients with thin corneas and in patients prone to flap dislocation such as military personnel or contact sports athletes. An increased understanding of the optics of refractive surgery and the corneal wound-healing response may help us to improve our results and modulate the patient's postoperative healing to further our goal of predictable, safe refractive surgery.

# LASIK

Patricia B. Sierra, David R. Hardten

# 3.4

**Definition:** Laser-assisted in situ keratomileusis (LASIK) is a form of lamellar corneal surgery that employs an excimer laser ablation of the corneal stroma beneath a hinged corneal flap.

## Key Features

- Combines lamellar surgery with the accuracy of the excimer laser.
- Hinged flap may be created either with a microkeratome or a femtosecond laser, however, femtosecond lasers produce thinner, more predictable flaps with fewer complications.
- Most widely used refractive surgery technique.
- Excellent option for refinement of refractive errors in pseudophakes especially with presbyopic and toric lenses.
- Recent advances including wave-front guidance, wavefront optimization, and topography guidance improve visual results and predictability.
- Recent rates of ectasia continue to fall due to better pre-operative screening and awareness.

## Associated Features

- PRK and other surface procedures are an alternative for patients in whom LASIK may not be ideal.
- Intraoperative ablation and postoperative complications.
- LASIK in complex cases: after radial keratotomy (RK), PRK, and penetrating keratoplasty.
- IOL after LASIK.

## HISTORICAL REVIEW

Refractive corneal surgery principles date back at least to the nineteenth century.<sup>1</sup> However, lamellar refractive surgery was not described until 1949, when Dr. José I. Barraquer realized that the refractive power of the eye could be altered by subtraction or addition of corneal tissue.<sup>2</sup> The term *keratomileusis*, which is derived from the Greek roots *keras* (hornlike = cornea) and *mileusis* (carving), was used to describe the lamellar techniques.<sup>3-5</sup> Unfortunately, there were many disadvantages to the procedure (i.e., complex instrumentation, steep learning curve, high rate of complications, and corneal scarring<sup>4</sup>), and the initial enthusiasm soon dissipated.

It was not until Dr. Luis Ruiz turned to keratomileusis in situ that the technical difficulties of the previous techniques were overcome. The introduction by Ruiz in the early 1980s of a microkeratome propelled by gears was a significant milestone for the development of modern refractive surgery. Dr. Leo Bores in 1987 performed the first keratomileusis in situ in the United States. This technique was still difficult to perform and had a significant complication rate.<sup>5,6</sup>

Within a few years, advances in instrumentation allowed for the lamellar keratoplasty to be performed with greater accuracy of the resections; this became known as automated lamellar keratoplasty (ALK). Results of ALK for myopia showed improvement over previous lamellar techniques but still were far from predictable, with significant induction of irregular astigmatism and reduction of best-corrected visual acuity (BCVA).<sup>7</sup>

The introduction of the excimer laser has had a greater impact on the practice of refractive surgery than any other event in the past 25 years.<sup>6</sup> Trokel et al. suggested PRK after studying the effect of the excimer laser on animal corneas in 1983.<sup>8</sup> It was later revealed that in myopia greater than 6.00 diopters (D), PRK resulted in significant central corneal haze, regression of the refractive effect, and poor predictability.

Buratto reported the use of the excimer laser in situ after a cap of corneal tissue was removed.<sup>9</sup> In a further improvement of his technique, Pallikaris came up with the idea of combining the precision of PRK with the technique of ALK and creating a hinged flap that was replaced after treatment of the lamellar bed with the laser.<sup>10-12</sup> In this way LASIK was introduced, designed, and developed at the University of Crete and the Vardinoyannion Eye Institute of Crete, Greece.<sup>12</sup> LASIK avoided the inaccurate positioning of the corneal cap, which produced significant irregular astigmatism. Guimaraes et al. then reported that suturing could be eliminated by briefly drying the flap.<sup>13,14</sup>

In summary, it was the combination of an old technique (keratomileusis) with new technology (excimer laser) that redefined corneal refractive surgery at the close of the twentieth century.<sup>9</sup> Buratto<sup>9</sup> and Pallikaris<sup>12</sup> are credited with combining lamellar surgical techniques developed by Barraquer<sup>2,5</sup> and excimer laser technology in a procedure they termed laser-assisted in situ keratomileusis.

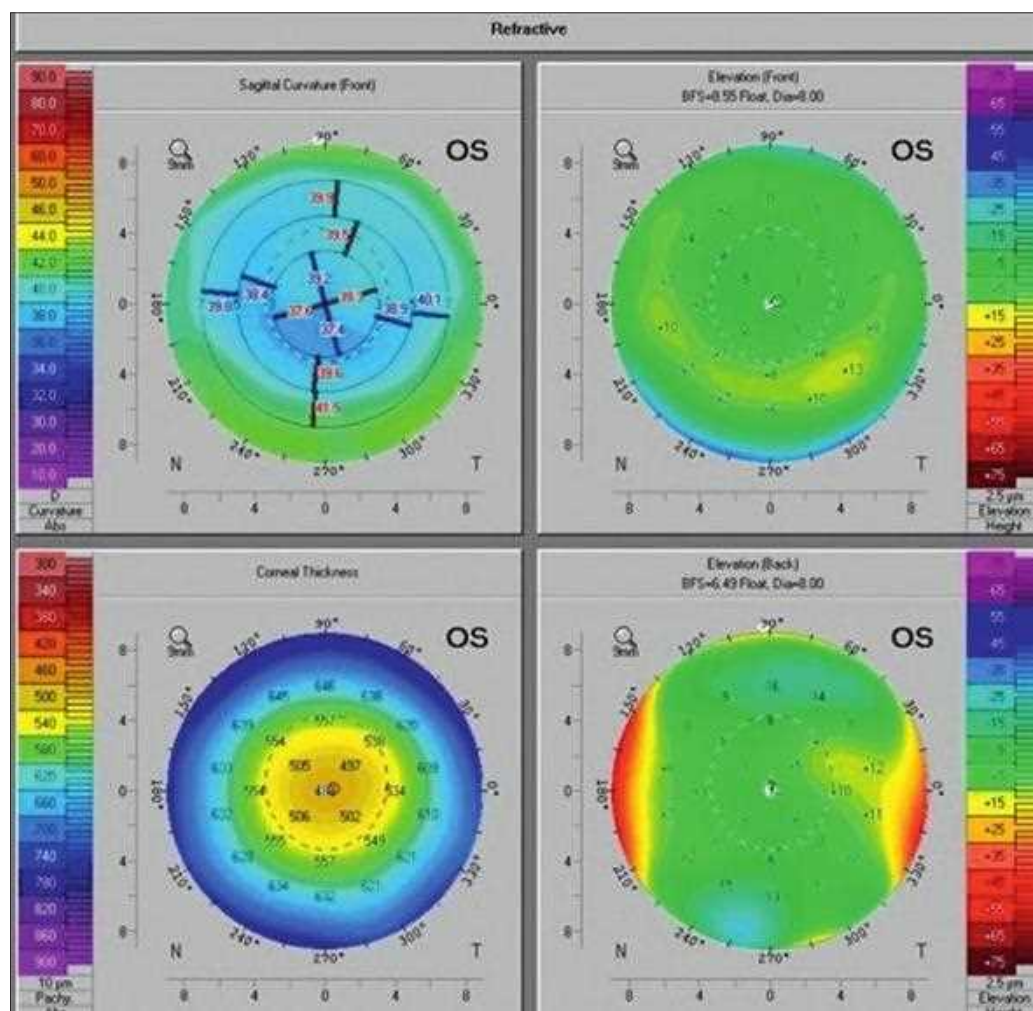

## LASIK

LASIK combines lamellar corneal surgery with the accuracy of the excimer laser. It involves the excimer laser ablation of the corneal stroma beneath a hinged corneal flap that is created with a microkeratome or a femtosecond laser.

LASIK has been used to correct up to 15.00 D of myopia, 6.00 D of hyperopia, and up to 6.00 D of astigmatism. The range of corrections utilized has not been clearly defined, and many surgeons have treated patients beyond these ranges with success. The results in the clinical evaluation of the procedure as far as predictability (percentage of eyes within a given postoperative target, i.e.,  $\pm 0.5$  D), efficacy (percentage of eyes with loss of best-corrected vision postoperatively, i.e., loss of two or more lines), stability (evaluation of stability of refraction at a certain interval postoperatively), and quality of vision (incidence of adverse visual phenomena, such as halos, glare, etc.) have been better in lower ranges than in higher ranges of correction.<sup>15</sup> Most surgeons now limit their levels of correction to less than 8.00–10.00 D of myopia and 4.00 D of hyperopia.<sup>16</sup>

The normal cornea has a prolate shape (greater curvature centrally than peripherally). Laser vision correction procedures for myopia reverse this natural prolate shape of the cornea and decrease the central corneal curvature to create an oblate shape (Fig. 3.4.1). Corneal surgery for hyperopia differs in several important respects from surgery for myopia. The corneal refractive power must be increased to treat hyperopia, whereas it must be decreased to treat myopia. Excimer laser ablations for treatment of hyperopia are applied in the midperiphery and result in steepening of the

**Fig. 3.4.1** Postmyopic LASIK With Scheimpflug Imaging. Note the central corneal flattening on sagittal curvature and anterior elevation maps with corresponding thinning on pachymetry map.

**Fig. 3.4.2** Posthyperopic LASIK Imaging on Placido Disc Topography. Note central corneal steepening.

central cornea and relative flattening of the periphery with minimal ablation occurring at the center of the cornea (Fig. 3.4.2). Effective treatments for hyperopia have a larger ablation diameter than those for myopia.

Hyperopic astigmatism treatment is accomplished with the excimer laser by removing tissue along the paracentral area, promoting steepening

of the flat meridian. Cylindrical ablation patterns for correction of mixed astigmatism include the bitoric and the cross-cylinder techniques. The bitoric LASIK technique consists of flattening the steep meridian with a cylindrical ablation in combination with a paracentral ablation over the flat meridian to steepen this axis. The cross-cylinder technique corrects astigmatism by dividing the cylinder power into two symmetrical parts. Half of the correction is treated on the negative meridian, and half is treated on the positive meridian.

## Excimer Lasers

The excimer laser is used to reshape the surface of the cornea by removing anterior stromal tissue. The process by which the excimer laser removes corneal tissue is nonthermal ablative photodecomposition.<sup>17</sup>

Laser delivery patterns include broad beam, scanning slit, and flying spot. Some lasers have a combination of mechanisms that allow for large and small treatment areas through a system termed variable spot scanning. This combines the advantage of a shorter treatment time by treating large areas all at once and the flexibility of treating smaller areas asymmetrically when needed with a small-diameter beam.<sup>18</sup>

There are four basic types of excimer laser treatment profiles: conventional, wavefront-optimized, wavefront-guided, and topography-guided.

*Conventional LASIK*, also called standard or traditional LASIK, was the first profile to receive Food and Drug Administration (FDA) approval and still is used commonly today. Conventional LASIK applies a simple spherocylindrical correction obtained through a manifest refraction and based on the removal of tissue using Munnerlyn's equation.<sup>19</sup> However, conventional LASIK to treat myopia induces positive spherical aberration dependent on the amount of attempted correction.<sup>20</sup>

In standard treatments, the best point to use for centration during the refractive procedure is still not clear, with the options of the corneal intercept of the visual axis, the entrance pupil, or the corneal light reflex.<sup>21,22</sup> Eye-tracking devices rely on infrared lasers or cameras to follow small eye movements and move the laser ablation beam accordingly.

Studies have shown improvements in uncorrected visual acuity (UCVA), BCVA, and centration with eye-tracking devices.<sup>23,24</sup> Larger ablations and blend zones may reduce the incidence of glare and halos.<sup>25</sup>

**Wavefront-guided (WFG) LASIK**, also called custom LASIK, is a variation in which the excimer laser ablates a sophisticated pattern based on measurements from an aberrometer. The goal of WFG LASIK is to achieve an improved ablation based on the optical aberrations measured with the wavefront aberrometer, not just sphere and cylinder (lower-order aberrations). There are other types of optical aberrations in the visual pathway of the eye, such as coma and spherical aberration, collectively called higher-order aberrations (HOA). Wavefront technology measures both the lower-order aberrations and HOA,<sup>26,27</sup> improving the precision of refraction to 0.1 D or smaller. There are several methods that can be used to measure the wavefront: Tscherning, dynamic skiascopy, ray tracing, and Hartmann-Shack. All methods evaluate how light is modified as it passes through the lens and cornea, and a wavefront is constructed by analyzing the exiting light rays. The shape of the wavefront describes the total aberration of the eye. The size of the wavefront (cross-sectional area) is determined by the size of the entrance pupil.

The first step in the wavefront-based LASIK technique is an examination with a wavefront device that measures the aberrations. The profile to correct these aberrations is created and imported into an excimer laser and used to guide the ablation during LASIK. (Fig. 3.4.3A). As the ablation patterns and treatments become more complex and more specific for the individual, the importance of precise registration of these patterns on the cornea increases. Significant cyclorotation could introduce significant postsurgical aberrations.<sup>22,28,29</sup> Iris registration is able to compensate for pupil centroid shifts due to variable illuminations and pupil sizes by referencing to the outer iris boundary with improved centration of wavefront ablations.<sup>30</sup>

The wavefront data can provide useful information in the postoperative setting, where it can be used to identify and describe specific HOA that may be consistent with a patient's subjective visual symptoms.

**Wavefront-optimized** treatment profiles are population-based corrections designed to reduce or eliminate the induced spherical aberration of conventional LASIK.<sup>31</sup> The wavefront-optimized treatment is based on a spherocylindrical correction that is adjusted by an internal algorithm to remove additional tissue in the periphery of the ablation zone, thereby creating a more prolate corneal shape.

In traditional myopic corrections, laser pulses at the peripheral cornea have a diminished effect due to the oblique angle of the laser beam, which induces spherical aberration. To compensate for this effect in a wavefront-optimized ablation, extra laser pulses are applied to the corneal periphery (Fig. 3.4.3B).<sup>32,33</sup>

**Topography-guided LASIK** uses information from both the corneal shape and the refractive spherocylindrical correction to determine the excimer laser ablation profile (Fig. 3.4.3C).

Topographers, which are not limited by pupil size, can measure greater and wider points of curvature on the cornea compared with wavefront devices. Topography-guided treatments can be used successfully for highly aberrated eyes (such as corneas with opacities or irregular astigmatism) and are not affected by the state of accommodation, early cataracts, or vitreous opacities.<sup>34</sup>

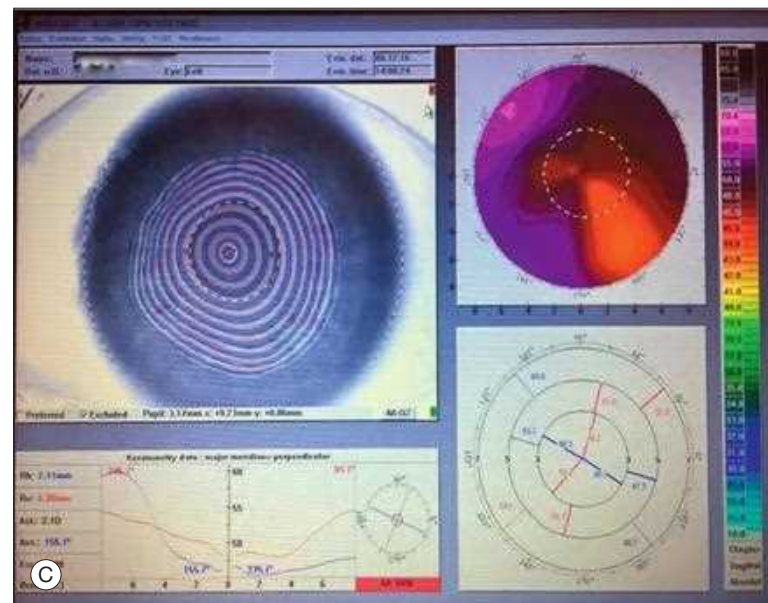

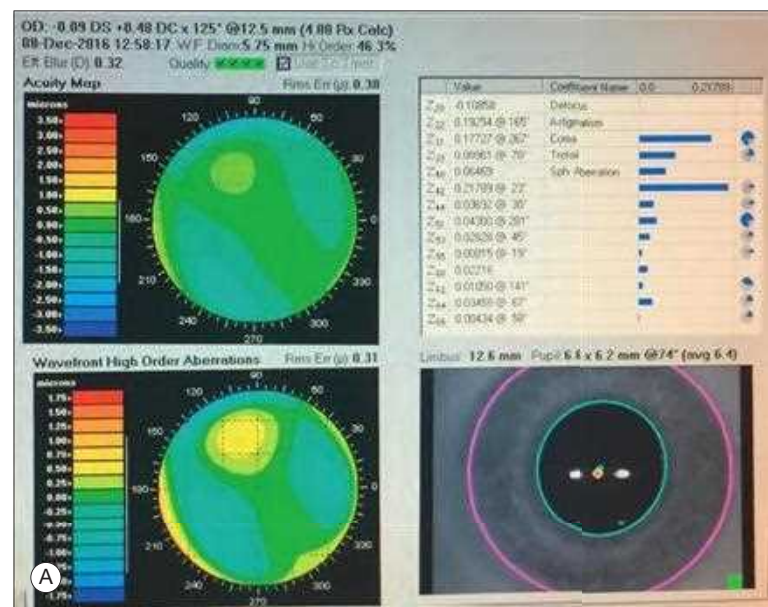

## Patient Selection

### Preoperative Evaluation and Diagnostic Approach

The first step in the evaluation should be to determine the goals of the patient in seeking refractive surgery and assess whether the patient has realistic expectations. Patients should understand the risks, benefits, and alternatives to the LASIK procedure. A stable refraction is important. Most surgeons now limit the upper range of correction to treatment of 8–10 D of myopia even though the lasers are capable of treating higher corrections.

Also important is a review of ocular and systemic conditions. Visual acuity is measured using manifest and cycloplegic refraction. The refraction is compared with prior spectacle corrections to assess the stability of refraction for the given eye. In addition, the wavefront refraction can be used as the baseline to obtain the wavefront-adjusted manifest refraction (WAMR). Pupil size, ocular dominance testing, and distance and near vision with and without correction should also be documented. Anterior and posterior segment examinations are performed to rule out other conditions that may adversely affect the surgical result.

Measurement of the central corneal thickness is an important element of the preoperative evaluation. WFG and optimized procedures usually remove more stromal tissue compared with conventional treatments. An

**Fig. 3.4.3 Wavefront-Guided, Wavefront-Optimized Ablations, and Topography-Guided Lasik.** (A) Wavefront-guided treatment plan based on aberrometry demonstrating lower and higher aberrations. Note: eye with significant degree of higher order aberrations despite low refractive error. (B) Wavefront-optimized treatments deliver additional pulses to the peripheral cornea to compensate for energy loss (beam ovalization and reflection) and decrease spherical aberration. (C) Topography-guided ablation. Overview display of patient's topographical data utilized to guide excimer laser treatment. Data include reduced camera image of measurement, keratometer data, color coded topographical image, and values.

estimated residual stromal bed is needed for surgical planning, because it is one factor that may predict postoperative ectasia. It is computed by subtracting the anticipated flap thickness and maximum ablation depth from the central corneal thickness measurement. The minimal residual bed for LASIK remains controversial, although 250–300  $\mu\text{m}$  is generally recognized as a minimum.

Ectasia can occur with even thick residual stromal beds in eyes with keratoconus features. To account for variations in actual flap thickness, the stromal bed can be measured after the flap has been retracted to allow for a more precise determination of the residual bed. A percentage of anterior tissue depth altered (PTA)  $\geq 40$  at the time of LASIK was significantly associated with the development of ectasia in a study of eyes with normal preoperative topography.<sup>35</sup>

Computer-assisted videokeratoscopy, corneal tomography, and Scheimpflug imaging are now available and used routinely in the preoperative and postoperative assessments of refractive surgery patients. These tools can help to screen for subclinical keratoconus or other corneal diseases.

Rigid contact lens wearers should remove their lenses for 3–4 weeks before examination, and soft contact lens wearers should have 2 weeks without lenses.

The possibility of monovision should be discussed with patients near or of presbyopic age; the discussion should include glare and halos, the possibility of under- and overcorrection, and any special considerations. Appropriate reading materials are helpful for patient education.

Informed consent should include a discussion of the most frequent side effects and potential risks involved with the surgery.

Alternative refractive treatments such as PRK should be discussed and may be preferred to LASIK in patients with anterior basement membrane dystrophy (ABMD), thin corneas, small and deep-set orbits, anterior scleral buckles, glaucoma after trabeculectomy, optic nerve disease, a risky occupation or activity, and corneal ectasia.<sup>36,37</sup>

The option of phakic IOL implantation can be offered to patients with high myopic corrections, very thin corneas, or abnormal corneal topography and/or tomography. Natural lens replacement is an option for patients nearing cataract age or requiring higher hyperopic corrections.

### Limitations and Contraindications

Laser vision correction may have a higher risk in patients with collagen vascular disease,<sup>38</sup> patients with autoimmune or immunodeficiency diseases, women who are pregnant or nursing, patients with signs of keratoconus, and those taking isotretinoin or amiodarone. Other conditions potentially associated with more adverse outcomes include Fuchs' corneal dystrophy, strabismus, ophthalmic herpes simplex or herpes zoster, and other systemic diseases likely to affect healing, such as diabetes and atopic disease.<sup>17,39–41</sup> Caution should be exercised for patients with abnormal corneal topographies or with ocular abnormalities as well as systemic conditions that are likely to affect wound healing.

## Microkeratomes and Femtosecond Lasers

A critical step in LASIK is the creation of the corneal flap. Several different microkeratomes are available for use in LASIK, ranging from modern automated steel microkeratomes to femtosecond lasers.<sup>42</sup> The choice depends on the surgeon's access and preference. In the past decade, the femtosecond laser has gained popularity and is replacing mechanical microkeratomes for LASIK flap creation in the United States.<sup>43,44</sup> Femtosecond lasers use laser pulses to cause microcavitation bubbles at a preset depth in the corneal stroma. The cavitation bubble is composed primarily of water and carbon dioxide. Multiple cavitation bubbles coalesce, and an intrastromal cleavage plane is created. Hinge placement, flap diameters, and flap thickness can be set to exact specifications. The chance of a flap buttonhole or incomplete, decentered, or free flap appears to be reduced. Flaps are thinner and of uniform thickness from the center to the periphery. Femtosecond flap creation is very precise and flap thickness is usually within  $\pm 14 \mu\text{m}$  of the intended result.<sup>43–45</sup> These differences in flap creation between femtosecond lasers and mechanical microkeratomes are thought to be responsible for better LASIK outcomes with the femtosecond laser.

## Operative Technique

Careful candidate selection, as discussed earlier, is critical for optimal outcomes. Surgeon preparation, including a thorough knowledge of the patient, procedure, parameters, and equipment, is essential. Patient preparation, including preoperative explanation regarding the steps, sights,

and sounds of the procedure, serves to maximize comfort and minimize anxiety. Approximately 5–10 minutes before the procedure, a mild sedative can be given to the patient to alleviate the anxiety of undergoing the procedure and to help them sleep postoperatively.

When performing a WFG LASIK procedure, obtaining an accurate capture of ocular aberrations is critical to ensure accurate measurements and optimal results (Fig. 3.4.3A).

### Microkeratome Surgical Technique

Topical anesthesia is applied to the eye. The eyelids are prepared with dilute povidone-iodine solution. A lid speculum is inserted to open the eyelids. Eyelashes should be kept away from the surgical field by the use of adhesive drapes or a closed bladed lid speculum. The contralateral eye is taped shut to prevent cross-fixation and drying. The microkeratome should be inspected for any defects in the blade or function of the moving parts. It is vital to confirm that the excimer laser will be able to deliver treatment after the corneal flap is reflected.

The cornea can be marked with ink before creating the corneal flap with the microkeratome to more easily realign the corneal flap in the event that a free flap is created.

The suction ring is placed using a bimanual technique in which the shaft of the suction ring is held in the fingers of one hand and a finger from the other hand provides additional support on the ring itself. Once adequate placement has been achieved, the suction is engaged by foot control (usually done by the technician). Adequate intraocular pressure (above 65 mm Hg) is then verified, with one useful method being an applanation lens (Barraquer tonometer). When adequate suction is achieved, the patient will confirm the temporary loss of visualization of the fixation light.

Before the pass of the microkeratome, several drops of artificial tears are placed on the cornea. This lubrication reduces the likelihood of a corneal epithelial defect occurring during the microkeratome pass. If using a two-piece microkeratome, the head is slid onto the post of the suction ring and advanced until the gear on the microkeratome head engages the track. It is important to again verify that the suction ring is still firmly attached to the globe at this point by gently lifting the suction ring upward, making sure that the suction is not lost. The surgeon then activates the microkeratome using forward and reverse foot control, the suction is turned off after the microkeratome pass, and then the suction ring can be carefully removed. Prompt attention at this point is extremely important in the case that a free cap or buttonhole has been created. In cases in which the stromal bed is too small or irregular for a good result, the laser ablation should not be performed, and the flap should be placed carefully back into position.

Before the flap is lifted, a wet cellulose sponge is used to prevent any cells, debris, or excess fluid from getting onto the stromal bed. With use of a flat cannula, iris sweep, or smooth forceps, the flap can be lifted and directed toward the hinge. Assessment of the thickness of the residual corneal bed may be performed by using ultrasound pachymetry. Microkeratome flap thickness may vary, with differences in thickness occurring even with the same microkeratome, making this measurement more important in eyes that may require a deeper ablation with the excimer laser, thus leaving less tissue in the residual corneal bed.

### Femtosecond Laser Flap Creation

The femtosecond laser is a highly precise, computer-guided laser that enables surgeons to program flap parameters, such as diameter, depth, hinge location, and edges, based on patients' anatomical characteristics or surgeons' preferences (Video 3.4.1). Flap parameters such as pattern, hinge position, flap depth, flap diameter, bed energy and spot separation, side cut angle and energy, hinge angles, and pocket parameters need to be carefully programmed or reviewed by the surgeon before the surgical procedure is initiated.

A suction ring is applied to the eye with slight downward pressure, and suction is then enabled to affix the ring firmly to the eye. Proper centration is extremely important and is a critical step that ensures greater accuracy of all subsequent steps of flap creation (Fig. 3.4.4). With the eye fixated, the cornea is then fully applanated. Centration and flap size should be confirmed on the monitor before the laser is initialized for treatment. It is critical to instruct the patient to abstain from eyelid squeezing during this step to prevent suction loss (Fig. 3.4.5A).

Once the procedure is complete, suction can be released and the same technique can be repeated on the contralateral eye.

Lifting femtosecond flaps can be quite different from lifting a microkeratome flap and is rather a blunt dissection, best accomplished with the use of a spatula (Fig. 3.4.5B). The spatula should be entered near the hinge

See clip:  
3.4.1

**Fig. 3.4.4** Suction Ring Centration Is a Critical Step That Ensures Accuracy of All Subsequent Steps of Femtosecond Laser Flap Creation.

**Fig. 3.4.6** Patient Fixation on Target Light Under Laser and Tracker Fixation on Pupil Width Should Be Maintained at All Times During Excimer Treatment.

and gently elevated in one to four swipes. The flap is then reflected, and the surgeon can proceed with excimer laser treatment.

### **Excimer Laser Ablation**

The patient should be positioned under the microscope with the head carefully aligned to make sure that the iris is perpendicular to the laser beam. Careful centration with the eye aligned in the x, y, and z planes is crucial. Alignment is even more critical with wavefront-guided laser treatments because most HOA are not radially symmetrical. Torsional misalignment—either cyclotorsion or head tilt—during surgery can result in undercorrection of the aberration or even in the induction of additional aberrations. The most basic technique to ensure alignment is to mark the limbus, typically at the 3 and 9 o'clock positions, immediately before surgery while the patient is seated. These marks are then used to align the head when the patient is lying under the laser. Most modern laser systems are now equipped with either pupil tracking or iris registration.

The surgeon should always verify the entered computer data before starting the ablation. The microscope should be adequately focused on the corneal surface. A dry cellulose sponge is then used to carefully remove any excess fluid from the stromal surface. Hydration of the stromal bed needs to be adjusted evenly and consistently in all cases. It is important at this point to minimize the procedure time in order to prevent stromal dehydration and subsequent overcorrection. Uneven hydration can lead to central islands and/or irregular astigmatism. Excess pooling of fluid often can be found near the hinge after folding back the flap and should be wicked away. The patient should be instructed to fixate on the target light. Adequate centration over the pupil should be reassessed (Fig. 3.4.6).

The laser eye tracker and iris registration are activated, and the laser ablation initiated. If fluid starts accumulating over the stromal surface, the laser ablation can be halted, and the fluid should be removed with a cellulose sponge. The hinge should be protected if it is within the ablation zone.

After the ablation, the flap is then repositioned onto the bed using an irrigation cannula or an iris sweep. Saline solution is used to remove debris from the interface (Fig. 3.4.7). A wet cellulose sponge is then used to realign the flap. Sweeping movements should be performed from the hinge toward the periphery of the flap.

Good adhesion of the flap is verified by stretching the flap toward the gutter. If good adhesion is present, there is minimal space in the gutter and no movement of the flap occurs when stroking the flap with a dry sponge. When the flap is felt to be securely in position, a drop of an antibiotic, a corticosteroid, and a lubricating agent may be applied to the cornea before removal of the speculum. If bilateral LASIK will be performed, the operated eye is covered and the procedure repeated in the contralateral eye. Both eyes are then protected with transparent plastic shields until the following day.

### **Postoperative Care**

Postoperative care of the typical patient who has undergone LASIK is still quite important. Generally, some tearing and burning occurs immediately

**Fig. 3.4.5** Raster pattern flap creation with Intralase femtosecond laser (A). Femtosecond flap dissection with blunt spatula. (B).

**Fig. 3.4.7 Irrigation Under the Flap Can Remove Debris From the Interface.** Care must be taken not to overirrigate, as this can increase the risk of flap striae from overhydration.

after surgery, for which it is recommended that the patient take a 2-hour nap. The patient is placed on topical prophylactic antibiotics and topical corticosteroids four times per day for 1–2 weeks. Preservative-free lubricating drops are helpful in most patients for the first several weeks after surgery, and frequent use should be encouraged.

On the first postoperative day, careful evaluation of the corneal flap should be performed at the slit lamp. The patient may resume most activities if the postoperative examination is normal. Instructions not to rub the eyes or swim underwater should be reinforced to prevent flap displacement or infectious keratitis.

## Complications

### Intraoperative Complications

An *incomplete flap* may result from the premature termination of the microkeratome advancement or ineffective passes or suction loss during a femtosecond flap creation. Reasons for a microkeratome incomplete pass include inadequate globe exposure due to interference of eyelid, lashes, speculum, and/or drape as well as loss of suction during the pass. If there is not enough room beneath the flap to perform the ablation, then the surgeon should reposition the flap and abort the surgery. Incomplete flaps also can result when the femtosecond laser cannot photodisrupt the corneal stroma in portions of the intended interface or if there is resistance between the interface from scar tissue. Typically, surface laser treatment with mitomycin-C can be used later to complete the refractive correction.<sup>46,47</sup>

When suction loss occurs during a femtosecond LASIK flap creation, resulting in an incomplete flap, a second femtosecond pass can create an intact flap. Tomita and colleagues reported successful immediate lamellar recut in their series of eyes with suction loss.<sup>48</sup> Some controversy surrounds the rationale for immediate recut, as other authors have demonstrated the potential for creating new cleavage planes if immediate recut is undertaken.<sup>49</sup> When suction loss occurs during the side cut or just before starting the side cut, a repeat side cut can be performed with a smaller diameter.

A *flap buttonhole* is one of the most serious flap complications, and the excimer laser ablation should be aborted. The flap should be repositioned and smoothed into place. Treatment of the second eye is not advisable at the same setting, as the same complication is likely to happen in the presence of a steep cornea or poor suction. However, these almost always occur in the second eye with a thinner flap in mechanical microkeratomers.<sup>50,51</sup> Femtosecond laser flaps also are prone to similar complications, albeit usually from a different mechanism: *vertical gas breakthrough*.<sup>52</sup> Epithelial ingrowth or haze may occur in the area of the buttonhole and may require further intervention. Typically, retreatment can be performed immediately or later with phototherapeutic keratectomy (PTK)/PRK and mitomycin-C.<sup>53,54</sup>

A *free cap* can occasionally occur when using a microkeratome to create a flap, and the surgeon should be prepared to deal with this problem. If the cap is small and/or decentered, it should be replaced without ablation and the procedure aborted. If it is well centered and of adequate size, the cap is typically placed on the conjunctiva with the epithelial side down during the

**Fig. 3.4.8 Opaque Bubble Layer (OBL).** Note gas bubbles trapped inside the stoma. The OBL can make lifting of the flap difficult and, if over the pupillary area, may interfere with an eye-tracking mechanism during excimer laser ablation.

photoablation. Care must be taken to reposition the cap into the same orientation after the ablation. Adequate drying time should be allowed for the cap to adhere without sutures. The most frequent cause of a free cap is a flat or small cornea in which there is less tissue to be brought forward into the microkeratome. Poor suction also can cause small free flaps. Marking of the cornea before flap creation can facilitate alignment in the event of a free cap.

*Epithelial defects* can be prevented with adequate lubrication of the cornea before the microkeratome pass. Also, toxic anesthetics should be kept to a minimum before the procedure. If a large epithelial defect occurs during the microkeratome pass, the ablation should be aborted in the affected eye. It is not recommended to proceed with flap creation in the contralateral eye, as the same complication is likely to occur. On the other hand, if the epithelial defect is small, a contact lens can be placed over the cornea to decrease significant discomfort to the patient. An epithelial defect may lead to greater flap edema with poorer adherence in the area of the defect, increasing the risk of epithelial ingrowth and diffuse lamellar keratitis.

*Epithelial breakthrough* is a rare complication during femtosecond laser corneal flap creation and is generally observed in patients with prior corneal incisions in the ablation zone. In these situations, increasing femtosecond energy or microkeratome flap creation should be considered. In patients with severe corneal scars that obscure visualization of anterior segment structures, femtosecond flap creation should be avoided. It is important to be attentive for this complication intraoperatively and to abstain from lifting the flap to prevent more serious flap problems such as buttonholes or flap tears.<sup>55</sup>

An *opaque bubble layer (OBL)* and anterior chamber gas bubbles can present during corneal flap creation with a femtosecond laser. An OBL forms when gas bubbles created by laser photocavitation are trapped inside the stoma. Gas also can appear in the anterior chamber and persist up to several minutes or even hours. The OBL can make lifting of the flap difficult, and care must be taken to perform a gentle blunt dissection to prevent a flap tear in the area of the OBL. If the OBL or anterior chamber bubbles are over the pupillary area, they may interfere with an eye-tracking mechanism during excimer laser ablation. In these situations, it is usually recommended to wait for bubbles to dissipate before proceeding with laser treatment.<sup>56</sup> Other factors associated with increased frequency of OBL include steeper, thicker corneas and a hard docking technique. Although the OBL makes the LASIK procedure more difficult, it does not appear to affect the postoperative optical quality and visual outcome (Fig. 3.4.8).<sup>57</sup>

### Ablation Complications

*Central islands* are small central elevations in the corneal topography that may occur for a variety of reasons.<sup>58,59</sup> Beam profile abnormalities, increased hydration of the central corneal stroma, or particulate material falling onto the cornea may block subsequent laser pulses. This was more common with broad-beamed lasers.<sup>60</sup> Typically these central islands resolve with time as epithelial remodeling fills in the surrounding area.

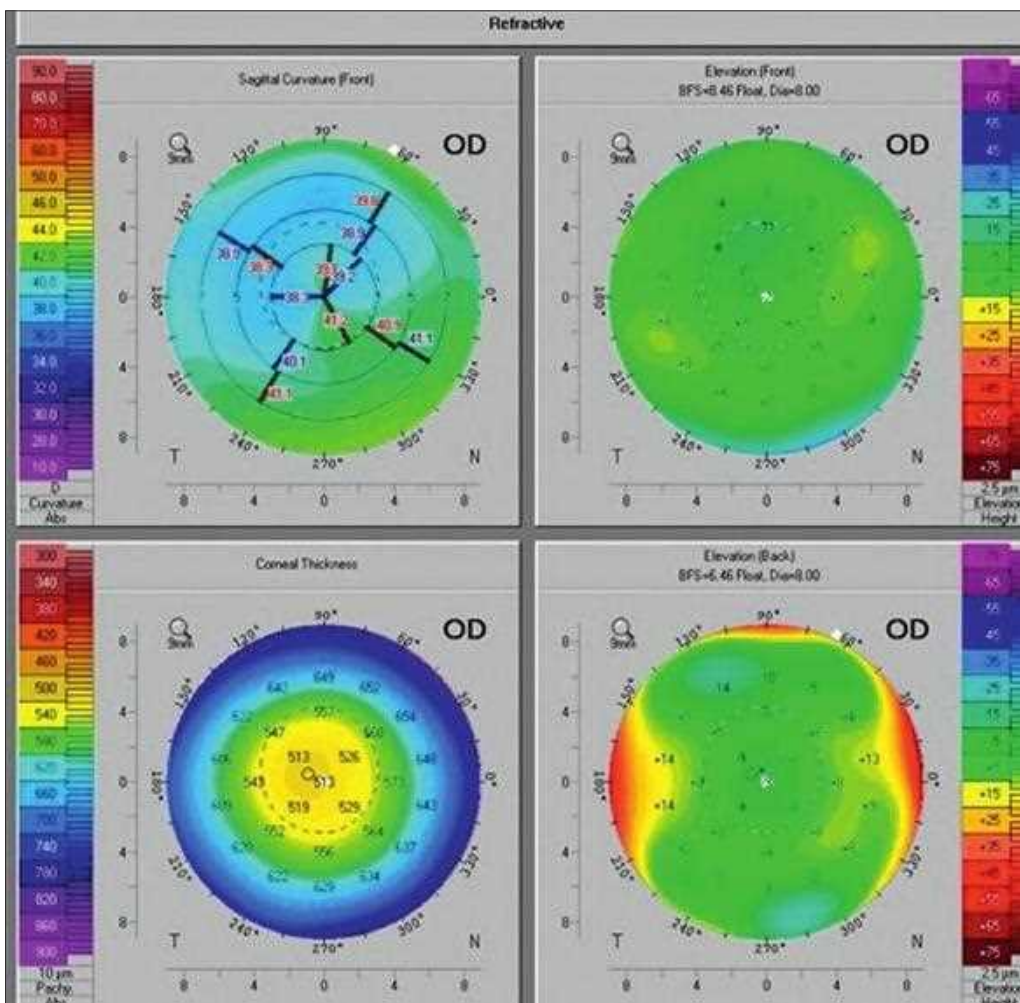

Fig. 3.4.9 Superior Decentration on Scheimpflug Imaging Following Myopic Excimer Ablation.

**Decentration** (Fig. 3.4.9) can result from poor fixation and alignment, eye movement during the laser procedure, significant pupil shift with light, or asymmetrical hydration of the cornea. The higher the myopic correction, the greater the risk of a decentered ablation, which can result in glare, irregular astigmatism, and a decrease in BCVA.<sup>22,61,62</sup> Low-contrast visual acuity is a more sensitive measurement of visual function than high-contrast Snellen acuity and can be used to assess these patients more accurately.<sup>63</sup> Decentration may be decreased with the use of current lasers with incorporated eye-tracking systems and iris registration, yet careful attention must still be paid to patient fixation.<sup>64</sup> Typically, if the ablation is more than 1 mm decentered, the irregular astigmatism that occurs is symptomatic. Management of decentration by treatment based on wavefront or topographical information may decrease symptoms in patients with an unsatisfactory outcome with the first procedure.<sup>65</sup>

**Under- and overcorrection** may result from errors of refraction, improper surgical ablation, malfunctioning of the excimer laser, abnormal corneal hydration status, or an excessive or inadequate wound-healing response. It is crucial to maintain consistent hydration of the cornea, because excessive fluid on the cornea results in an undercorrection. If desiccation of the corneal stroma is present, then overcorrection and haze may occur. The higher the refractive error, the greater the chance of regression.<sup>63</sup> Many surgeons find that adjusting the amount of treatment using a nomogram based on their actual surgical results improves their refractive outcomes.

### Postoperative Complications

**Interface debris** is common even with aggressive interface irrigation. The most frequent source of debris is meibomian gland material from the lids that is trapped in the interface. Careful draping of lashes and cleaning of the flap interface with balanced salt solution before and after the flap is floated into position can help to reduce the incidence of this problem.<sup>66</sup>

**Flap displacement** usually occurs in the first 24 hours postoperatively. When a flap displacement occurs, it should be lifted and repositioned as soon as possible.<sup>67</sup> The epithelium at the flap edge grows remarkably fast to cover the stromal bed. Care must be taken to clean the bed and back of the flap of debris and epithelial cells. Stroking the cap with a cellulose

sponge can minimize persistent folds in the flap and properly line up the cap with the bed.

**Punctate epithelial keratopathy** (dry eye) is the most frequent complication of LASIK.<sup>68</sup> Several possible mechanisms contributing to LASIK-induced dry eye have been proposed. The mechanisms include injury to the afferent sensory nerve fibers, a reduction in neurotrophic influences on epithelial cells, a decreased blinking rate, decreased tear production, altered tear-film stability and distribution, increased tear evaporation, and injury to limbal goblet cells. The preponderance of data supports the hypothesis that the most important factor in the pathophysiology of LASIK-induced dry eye is the transection of afferent sensory nerves in the anterior third of the stroma during the lamellar cut.<sup>69,70</sup> The disorder tends to be more common and more severe in the context of underlying chronic dry eye. It has become evident, however, that the disorder is multifactorial.<sup>71,72</sup> Studies in patients in whom the flap was created with a microkeratome showed significantly more signs and symptoms of LASIK-induced dry eye than those in which a femtosecond laser was used for flap creation.<sup>73</sup> Treatment involves frequent lubrication of the ocular surface with artificial tears, topical anti-inflammatory therapy, and punctal plugs; management of any eyelid disorder also may be of benefit.

**Diffuse lamellar keratitis** (DLK), also known as *Sands of Sahara syndrome*, is an interface inflammatory process that occurs in the early postoperative period after LASIK (Fig. 3.4.10).<sup>74</sup> Patients are initially asymptomatic and often have no visual impairment. A fine granular-appearing infiltrate that looks like dust or sand typically presents initially in the interface periphery. If left untreated, the inflammation can progressively worsen and may lead to corneal scarring with resultant irregular astigmatism. The cause of DLK is likely multifactorial. Bacterial toxins or antigens, debris on the instruments, eyelid secretions, or other factors may play a role.<sup>74-77</sup> Femtosecond LASIK flap creation has been associated with a higher risk for DLK than microkeratome flap creation.<sup>78</sup> Studies suggest that newer generation femtosecond lasers with higher frequency are associated with decreased DLK rates because lower energy settings are used in creating LASIK flaps.

Treatment involves frequent topical corticosteroids, and if severe enough, interface irrigation.<sup>79,80</sup> However, some authors have reported

**Fig. 3.4.10 Diffuse Lamellar Keratitis (DLK).** The image shows stage II DLK, and identification of this should be followed by increased topical corticosteroid administration and close follow-up.

excellent results in the treatment of severe DLK with high-dose topical and oral corticosteroids without flap lifting and interface irrigation.<sup>81</sup>

*Flap striae and microstriae* are common complications after LASIK. Most striae are asymptomatic and can be visualized if the flap is carefully examined with retroillumination.<sup>66</sup> When microstriae occur over the pupil or when macrostriae exist, irregular astigmatism with visual aberrations and monocular diplopia may result. In such cases, the flap should be lifted again, hydrated, and stretched back into position.

*Epithelial ingrowth* into the interface between the flap and the stromal bed occurs in up to 3% of patients following myopic LASIK surgery (Fig. 3.4.11). Known risk factors for this complication include epithelial defects at the time of surgery, history of recurrent corneal erosions, corneal basement membrane epithelial dystrophy, history of ingrowth in the other eye, hyperopic LASIK correction, flap striae or folds (as when the flap dislocates after surgery because of trauma or poor adhesion), flap instability, type 1 diabetes, and repeated LASIK surgeries.<sup>82,83</sup> Rarely, the epithelial ingrowth progresses into the central visual axis, causing irregular astigmatism and loss of BCVA. In some cases, the epithelial cells will block nutritional support for the overlying stroma and lead to flap melt.<sup>66</sup> If this is the case, the flap should be lifted, and careful scraping of the epithelium should be performed at the stromal bed as well as under the flap. In recurrent cases, suturing or flap gluing may help to reduce the incidence of recurrent epithelial ingrowth.<sup>84</sup> Nd:YAG laser application has been described as a technique for the treatment of epithelial ingrowth after LASIK surgery.<sup>85</sup>

*Corneal haze* can occur following LASIK. With fears of corneal ectasia following LASIK, surgeons continue to aim for thinner flaps. Although thin-flap LASIK has been reported to be successful,<sup>86</sup> there have been reports of interface haze formation with thin-flap femtosecond LASIK (<90  $\mu\text{m}$ ), especially in young patients<sup>87</sup> and could be related to focal disruptions of the Bowman's layer and injury to the epithelial basement membrane.<sup>88</sup>

*Infectious keratitis* after LASIK is a devastating, vision-threatening complication. Fortunately, the estimated incidence is low and reported to be between 1 in 1000 and 1 in 5000 procedures.<sup>89,90</sup> Reported organisms include *Mycobacterium* spp., fungi, *Nocardia* spp., *Staphylococcus aureus*, *Streptococcus viridans*, coagulase-negative *Staphylococcus* spp., and *Streptococcus pneumoniae*.<sup>91</sup> The most common organism cultured in a worldwide survey was methicillin-resistant *Staphylococcus aureus* (MRSA).<sup>93</sup> Symptoms may include pain, photophobia, watering, decreased visual acuity, ghost images, and halos. Slit-lamp examination may reveal ciliary injection, epithelial defect, anterior chamber reaction, and hypopyon. In the case of mycobacteria and fungi, presentation is usually delayed several weeks after the LASIK procedure and then has a smoldering course. Clinically, the mycobacteria and fungi usually are seen in the interface, often with a feathery or indistinct margin. Gram-positive infections are usually seen shortly after the procedure, often at the flap margin, and usually have distinct, sharp margins.

It is important to maintain a high suspicion for atypical organisms. The flap should be lifted and cultures should be inoculated on blood, chocolate, Sabouraud and Lowenstein-Jensen agar, and blood-heart infusion. Smears

**Fig. 3.4.11 (A)** Central epithelial ingrowth under LASIK flap following traumatic flap displacement. **(B)** Peripheral epithelial ingrowth with associated flap melting.

should also be taken for Gram, Giemsa, and Calcofluor white stains as well as Ziehl-Neelsen for acid-fast bacteria.

The mycobacteria species associated with keratitis following LASIK belong to the nontuberculous mycobacteria group. These species are resistant to chemical disinfectants such as chlorine, which is probably why such infections may occur after surgical procedures. Clarithromycin and amikacin are the antibiotics of choice, but poor penetration of topical medications leads to persistent infection. Early flap lifting and soaking of the flap and bed with amikacin 0.08% and/or clarithromycin 1% followed by aggressive topical therapy leads to the best results.<sup>92</sup>

Perhaps the most important factor within our control is prevention. Meibomian gland disease should be treated before LASIK. Instruments must be properly sterilized, and intraoperative sterile techniques should be employed, including the use of sterile gloves and drapes and disinfection of the skin and eyelids with povidone-iodine. During the procedure, instruments should be sterile and sterile plastic bags used for the nonsterile portions of the laser. Efforts should be made to avoid irrigating meibomian secretions into the interface. Suction lid specula may be helpful in removing excessive fluids and debris. Postoperatively, the patient should be instructed to wear shields and not to rub the eye. Prophylactic antibiotics should be used for 1 week postoperatively.

### Keratectasia

Retrospective analysis of patients with ectasia suggests the following risk factors for progression of ectasia after laser vision correction: (1) abnormal preoperative topography, (2) low residual bed thickness, (3) young age, (4) low preoperative corneal thickness, and (5) high myopia.<sup>94,95</sup> General agreement exists on leaving 250–300  $\mu\text{m}$  of untouched posterior cornea stroma. Ablation below that limit may cause biomechanical weakening, causing the cornea to bulge forward.<sup>96</sup> Another important cause of iatrogenic keratectasia is LASIK performed on unrecognized keratoconus suspects.<sup>97</sup> Videokeratographic clues for a keratoconus suspect may include steep

keratometry, inferior steepening of the cornea, asymmetry of the corneal curvature, or nonorthogonal astigmatism. Iatrogenic keratectasia has been reported as early as 1 week and as late as 2 years postoperatively.<sup>98</sup>

Although ectasia is rare after laser vision correction, many management options are available. Most are similar to those available for naturally occurring keratoconus. Most patients can still function well with nonsurgical options, such as contact lenses.<sup>99,100</sup> Intracorneal ring segments may be used to manage patients with ectasia after refractive surgery.<sup>101–103</sup> Corneal collagen crosslinking (CXL) with riboflavin and ultraviolet-A (UVA) radiation is now being used to treat keratoconus and post-LASIK ectasia; the principal goal of the technique is to stabilize the progression of these corneal diseases.<sup>104,105</sup> In previous studies of CXL outcomes, patients had improvement in corrected distance visual acuity (CDVA), uncorrected distance visual acuity (UDVA), maximum and average keratometry (K) values, several corneal topography indices, and corneal and optical HOA.<sup>106–108</sup>

Although corneal transplantation (penetrating or lamellar) is not often required, transplantation does have a high rate of success in eyes with keratoconus and would likely yield similarly good results in eyes with ectasia after refractive surgery.<sup>109,110</sup>

## Results

The efficacy and predictability of laser refractive surgery have greatly improved in recent years, even with standard conventional techniques. Most of this improvement is due to the development of flying spot lasers,<sup>18,111</sup> tracking systems,<sup>112,113</sup> and 8- to 9-mm transition zones that allow for blending the steep step at the periphery of the ablation zone.<sup>114,115</sup>

With traditional LASIK, the accuracy is greater for lower degrees of myopia. In one study of 130 eyes with an average preoperative spherical equivalent (SE) of  $-3.61$  D followed for 12 months after LASIK, 98% obtained a correction within  $\pm 1$  D from target and 93% obtained 20/40 or better UCVA.<sup>116</sup>

Another study showed that in low myopia ( $-0.75$  D to  $-6.00$  D of myopia and  $0$ – $0.75$  D of preoperative astigmatism), 50% of eyes achieved 20/25 or better and 90% of eyes achieved 20/40 or better at 1 month postoperatively, and the SE was within  $\pm 1.00$  D of emmetropia in 89% of the patients. In high myopia ( $-6.00$  to  $-20.00$  D of myopia and  $0$  to  $4.5$  D of preoperative astigmatism), at 1 month, 35% of eyes were 20/25 or better and 71% of eyes were 20/40 or better, and the mean SE was within  $\pm 1.00$  D of emmetropia in 63%.<sup>117</sup> The results of this and other studies suggest more predictable results for low myopia without astigmatism than for high myopia correction or in eyes requiring astigmatic correction.<sup>118,119</sup>

Data obtained from multicenter trials on wavefront-guided LASIK ablation for low to moderate myopia and astigmatism revealed that 98% of eyes achieved 20/20 UCVA, and 71% were at 20/16 or better uncorrected. What is even more impressive is the fact that postoperative UCVA was better than the preoperative best corrected results in 47% of patients.<sup>120,121</sup>

Ongoing improvements in the custom wavefront treatments have resulted in more precise treatments and postoperative results even for higher corrections. The results achieved with VISX Star S4 laser (Advanced Medical Optics, Inc.; Santa Ana, CA) treatment of high myopia and astigmatism with Custom Vue customized ablations were remarkable. The mean preoperative refractive spherical error was  $-8.00$  D ( $\pm 1.4$  D, range  $-5.5$  to  $-11.3$  D). The average cylinder was  $-1.00$  D ( $\pm 1.00$ , range  $0.0$  to  $-5.3$  D). The manifest refraction spherical equivalent (MRSE) was  $-8.5$  D ( $\pm 1.3$ , range  $-6.4$  to  $-11.8$  D). At 6 months, 98% of the eyes were seeing 20/40 or better uncorrected, 84% were 20/20 or better, and 65% were 20/16 or better. Three quarters had the same or better postoperative UCVA compared with their preoperative best spectacle-corrected visual acuity (BSCVA). Among the spherical myopes, 99% were at 20/20 or better uncorrected, with 84% at 20/16 or better at 6 months. Patients' satisfaction with their quality of vision was also high. This demonstrated that the customized approach offers excellent quantity as well as quality of vision even for higher corrections.<sup>120</sup>

Low to moderate levels of spherical hyperopia, simple hyperopic astigmatism, and compound hyperopic astigmatism can be effectively and safely corrected with LASIK. The results of a study evaluating patients with primary and secondary hyperopia who underwent traditional LASIK demonstrated that patients with primary hyperopia and a mean manifest SE of  $+1.73 \pm 0.79$  D before surgery obtained a postoperative SE of  $-0.13 \pm 1.00$  D at 6 months after surgery and an SE of  $-0.18 \pm 1.08$  D at 1 year after surgery. At 6 months, 84% of patients with secondary hyperopia had a UCVA of 20/40 or better; 76% were within  $\pm 1$  D of emmetropia. At 1 year, 85% had a UCVA of 20/40 or better and 85% were within  $\pm 1$  D of emmetropia. No patients with secondary hyperopia lost two or more

lines of BCVA at 1 year.<sup>122</sup> For higher levels of correction, the predictability within  $\pm 1$  D of attempted correction decreases to approximately 50%–80%, and the loss of BCVA generally ranges from 0% to 7%. However, LASIK for hyperopia greater than  $+5.00$  D is not recommended, as it may result in a loss of BSCVA in a significant number of eyes (13%–15%).<sup>123–128</sup>

Multicenter clinical trials of wavefront-guided LASIK for the correction of hyperopia and hyperopic astigmatism demonstrated significant improvements compared with traditional LASIK. Mean preoperative spherical error was  $+1.67 \pm 1.00$  (up to  $+4.59$  D), the average astigmatism was  $+0.65 \pm 0.48$  D (up to  $+2$ ), and MRSE was  $+1.99 \pm 1.00$  D (up to  $4.84$  D). At 6 months, 95% of the eyes had a UCVA of 20/40 or better, 62% were at 20/20 or better, and 20% were at 20/16 or better. The UCVA at 9 months was 20/16 or better in 24% of eyes and 20/20 or better in 72% of eyes.<sup>120</sup>

For mixed astigmatism, multicenter trials for custom wavefront LASIK results 6 months after surgery were a UCVA of 20/40 or better in 96% of eyes and 20/20 or better in 60% of eyes.<sup>120</sup>

Wavefront-guided and wavefront-optimized procedures attempt to minimize induced aberrations in different ways. Aspherical or wavefront-optimized ablation profiles have been developed to avoid inducing spherical aberrations.<sup>129,130</sup> Stonecipher and Kezirian reported 3-month results of an FDA trial for LASIK with the Allegretto Wave comparing wavefront-optimized versus wavefront-guided LASIK for myopic astigmatism, finding no statistically significant differences between either treatment group in regard to visual acuity and refractive outcomes. They stated that 93% of patients in each group had achieved 20/20 vision or better.<sup>131</sup> These results are comparable to those reported in a prospective, randomized study by Mirafat et al., who compared wavefront-guided and wavefront-optimized LASIK in contralateral eyes with myopia up to 7.00 D and astigmatism up to 3.00 D, also reporting no statistical differences in the UCVA, BCVA, or contrast sensitivity between both groups with 20/20 vision or better in 83.8% of the wavefront-optimized eyes and 89.2% of the wavefront-guided eyes.<sup>132</sup>

Stonecipher and Kezirian concluded in their study that wavefront-guided treatments may be considered if the magnitude of preoperative root mean square (RMS) HOA is  $>0.35$   $\mu\text{m}$ , and in their study population, 83% of eyes had preoperative RMS HOA of  $<0.3$   $\mu\text{m}$ .<sup>131</sup>

Studies using topography-guided LASIK have been encouraging. A prospective study of topography-guided LASIK using the WaveLight Allegretto Wave Eye-Q Laser included 249 eyes of patients with up to  $-9.00$  D of SE myopia at the spectacle plane with up to 6.00 D of astigmatism. Topography-guided treatment resulted in a significant reduction in MRSE and cylinder, reaching stability at 3 months after treatment. The mean MRSE was  $0.06 \pm 0.33$  D at 3 months and  $0.00 \pm 0.2700$  D at 1 year. At 1 year, 94.8% of eyes were within 0.50 D of plano. At 1 year, 15.7% of eyes saw 20/10 or better without correction; 34.4% of eyes saw 20/12.5 or better; 64.8% of eyes saw 20/16 or better; 92.6% of eyes saw 20/20 or better; and 96.5% of eyes saw 20/25 or better. Eyes treated with topography-guided treatment achieved an improvement in UCVA compared with preoperative BSCVA, with 29.6% of eyes gaining one or more lines of UCVA and 89.9% of eyes seeing at least as well without correction postoperatively as they did with best spectacle correction preoperatively.<sup>133</sup>

In a comparative study, both topography-guided and wavefront-optimized LASIK for myopia in virgin eyes provided excellent results. However, topography-guided LASIK was associated with better contrast sensitivity, lower induction of HOA, and a smaller amount of tissue ablation.<sup>134</sup>

With regard to patient satisfaction following LASIK, a comprehensive literature review was conducted in 2008 by the Joint LASIK Study Task Force. The results showed that 95% of patients were satisfied with their visual outcome after myopic and hyperopic LASIK.<sup>135</sup>

Modern LASIK outcomes support the safety, efficacy, and patient satisfaction of the procedure and appear better than those reported in summaries of the safety and effectiveness of earlier laser refractive surgery systems approved by the FDA. In a recent literature review of LASIK articles published between 2008 and 2015, the aggregate loss of two or more lines of corrected distance visual acuity was 0.61% (359/58653). The overall percentage of eyes with a UCVA better than 20/40 was 99.5% (59503/59825). The SE refraction was within  $\pm 1.00$  D of the target refraction in 98.6% of eyes (59476/60329), with 90.9% (59954/65974) within  $\pm 0.50$  D. In studies reporting patient satisfaction, 1.2% (129/9726) of patients were dissatisfied with LASIK.<sup>136</sup>

In addition, Price et al. compared visual satisfaction between LASIK and contact lens wear over a 3-year period. Current LASIK technology improved ease of night driving, did not significantly increase dry eye symptoms, and resulted in higher levels of satisfaction at 1, 2, and 3 years of follow-up.<sup>137</sup>

## LASIK ENHANCEMENTS

The initial consideration when deciding to perform a LASIK enhancement is to determine the possible reason for failure of the prior procedure. Errors may be related to inadequate preoperative refraction, improper laser ablation, abnormal corneal hydration during the procedure, an excessive or inadequate healing response, or induced corneal ectasia. A careful analysis of anterior and posterior corneal elevation maps should be performed to rule out a decentered ablation or iatrogenic corneal ectasia.<sup>138,139</sup>

Patient selection and appropriate timing are key for a successful LASIK enhancement. It is recommended to wait at least 3 months before considering an enhancement.<sup>140</sup> Patients with refractive instability should not undergo an enhancement procedure.

Another important consideration is the measurement of the central corneal thickness. If less than 250–300  $\mu\text{m}$  of residual untouched stromal bed will be available after the enhancement laser ablation or PTA is less than 40%, the risk of inducing corneal ectasia probably outweighs the benefit of the procedure.<sup>35</sup>

Regarding the decision of whether to recut the cornea versus lift the flap, studies have shown the effectiveness and predictability of using different techniques.<sup>141,142</sup> Flap lifting is probably the preferred method in most patients.<sup>143</sup> The flap edge can be marked at the slit lamp and lifted before the laser ablation. Unfortunately, this method requires flap manipulation and has been reported to be associated with a higher risk for epithelial ingrowth.<sup>143,144</sup> Flap recutting, however, may be associated with a higher risk of an inadequate flap or in loose lamellar wedges of stromal tissue. Therefore it is recommended to relift a flap when performing early enhancements in most patients. Some surgeons, however, advocate a deeper cut to avoid the previous interface.<sup>145</sup>

Femtosecond laser-created flaps are significantly stronger than microkeratome-created flaps and may be associated with increased difficulty of flap lift and a higher risk of complications.<sup>146,147</sup> To avoid these difficulties and possible complications of relifting or recutting LASIK flaps, a newer alternative is to utilize a femtosecond laser for the creation of a second side cut, within the border of the original LASIK flap (i.e., smaller than the original flap diameter).<sup>148</sup> Despite some reports of good results, epithelial ingrowth or irregular flaps can still result, and therefore most surgeons do not utilize these techniques.

A third alternative to flap lifting or recutting is PRK with the use of mitomycin-C on the LASIK flap.<sup>149</sup> This is a less invasive technique for the correction of residual refractive errors in patients with low residual stromal bed or in patients seeking an enhancement 2 or more years after the initial LASIK procedure, even though it is associated with a longer recovery.<sup>150,151</sup>

## LASIK IN COMPLEX CASES

### LASIK After Radial Keratotomy

Various studies have proven LASIK to be safe and effective in treating residual myopia and RK-induced hyperopia.<sup>152,153</sup>

A stable refraction for at least 6 months before LASIK is mandatory. A careful evaluation of the RK incisions is mandatory because the presence of epithelial inclusion cysts can predispose the patient to subsequent epithelial ingrowth after LASIK; LASIK should be avoided in these patients.

During the LASIK procedure, the flap should be manipulated with extreme care to prevent the RK incisions from splaying.<sup>154</sup> Careful observation of the patient during the postoperative period should be granted, as the risk of epithelial ingrowth is higher in this group of patients.<sup>155</sup> The epithelial ingrowth can be particularly difficult to manage and may even require fibrin glue for effective treatment.<sup>84</sup> With the availability of mitomycin-C to reduce haze in patients having PRK after prior surgery, many surgeons are now using PRK to treat patients with residual refractive errors after RK.<sup>156–158</sup>

### LASIK After Photorefractive Keratectomy

PRK has been proven to be a safe and effective method for treating low to moderate myopia.<sup>159</sup> Regression as well as the development of corneal haze are the main limiting factors in the correction of higher refractive errors, which are greater in patients treated for more than 6.00 D of myopia.

PRK retreatment for undercorrections should be approached with caution because there is a risk of further regression, increased haze, and loss of visual acuity.<sup>160,161</sup> LASIK appears to be a better approach in this

group of patients, and it has been proven to be a safe, effective, and predictable procedure for treating eyes with no or low haze after PRK.<sup>162</sup> Some surgeons suggest that the postoperative care should be the same as after primary PRK, with prolonged use of topical corticosteroids.<sup>163</sup>

In most cases, though, because of the underlying process that led the surgeon to decide on PRK in the first procedure (thin corneas, ABMD), the authors typically utilize PRK for enhancement procedures.

## LASIK After Penetrating Keratoplasty

Residual refractive errors after penetrating keratoplasty (PKP) are usually responsible for decreased visual acuity despite a clear graft. The mean amount of astigmatism that has been reported after PKP for keratoconus is usually between 2 and 6 D with only 15%  $>5.00$  D.<sup>164</sup> Visual rehabilitation with spectacles or contact lenses should be considered initially, followed by the possibility of incisional refractive surgery if the patient is intolerant to either of these alternatives.

Several studies have shown that LASIK has significant advantages over other surgical procedures in the management of refractive errors after PKP.<sup>165–170</sup>

LASIK should be delayed at least 12 months after PKP because of the risk of corneal dehiscence during the creation of the flap. Although the precise safety interval between PKP and LASIK has not been established, some surgeons have performed LASIK as early as 8 months after PRK,<sup>171</sup> while others advise a minimum period of 2–3 years.<sup>167,168</sup> All sutures should be removed before performing the lamellar surgery.

LASIK is more effective in treating myopia than astigmatism after PKP. In a study by Donnenfeld et al., the mean SE of patients before surgery of  $-7.58 \pm 4.42$  D improved to  $-1.57 \pm 1.20$  D at 12 months after LASIK. Also, the mean cylinder of  $3.64 \pm 1.72$  D before surgery improved to  $1.29 \pm 1.04$  D by 12 months after. SE anisometropia was reduced from a mean of  $6.88 \pm 4.4$  D to  $1.42 \pm 1.05$  D at the final examination. BCVA remained the same or improved in 21 of 23 eyes and decreased by one and three lines in two patients.<sup>171</sup>

Our experience in 57 eyes treated for myopia and astigmatism after PKP was a mean SE decrease from  $-4.19 \pm 3.38$  D (range,  $-0.75$  D to  $-15.25$  D) preoperatively to  $-0.61 \pm 1.81$  D 2 years after LASIK. The mean preoperative refractive astigmatism decreased from  $4.51 \pm 2.2$  D (range,  $0.5$ – $10.00$  D) to  $1.0 \pm 1.35$  D for the 28 eyes with follow-up. The UCVA was 20/40 or better in 12 eyes (43%), and the BCVA was 20/40 or better in 86%.<sup>169</sup> These results are very similar to those of a recent study by Malecha et al. in which the preoperative SE was reduced by 3.93 D and the mean cylinder was reduced by 2.83 D from the preoperative values at the last follow-up visit. The UCVA was 20/40 or better in 73.7% of the eyes after LASIK.<sup>172</sup> The long-term results also appear to be quite stable in most eyes.<sup>171</sup>

In conclusion, LASIK after PKP is in general less predictable than in eyes with no history of surgery, partly because of larger corrections and the effect of the graft–host interface.<sup>171</sup> Still, significant improvement in uncorrected vision as well as anisometropia make this treatment attractive for patients with a healthy endothelium and a transplant large enough to place the ablation within the transplanted cornea. It is important to remember that the realistic goals of LASIK after PKP are to decrease the degree of anisometropia and ametropia to levels at which spectacle correction or contact lenses can be tolerated.

## LASIK After Intraocular Lens Implantation and Bioptics

Bioptics, popularized by Roberto Zaldivar, is the planned combination of phakic or aphakic IOL surgery with corneal surgery to correct large refractive errors.<sup>173</sup> Typically the maximum IOL power is used, and the residual refractive error is corrected by corneal ablation surgery (PRK or LASIK). The surgeries can be staged, with the lens surgery performed first followed later by PRK or LASIK. Alternatively, the LASIK flap can be made before the time of the lens surgery and lifted several weeks or months later for the laser ablation. Bioptics can be performed with either phakic or aphakic IOLs to correct any residual refractive error. Bioptics is especially useful in high myopia with astigmatism, and it is preferable to laser corneal ablation alone because of the reduced risk of visual aberrations, contrast loss, glare, and halos that are associated with extremely large myopic laser ablations.<sup>174,175</sup>

Similarly, LASIK can be extremely useful in treating ametropia after clear lens extraction or cataract surgery with multifocal IOL implantation with good refractive outcomes and improved patient satisfaction.<sup>176,177</sup>

## Intraocular Lens Calculations After LASIK

Postrefractive surgery patients who develop a cataract expect excellent UCVA after cataract surgery, just like after their previous refractive procedure. Experience with eyes after myopic refractive procedures indicates that use of postoperative average standard keratometric readings in standard IOL power predictive formulas frequently results in substantial refractive errors, hyperopia being the unexpected surprise in patients who undergo myopic refractive procedures, and myopia in those undergoing hyperopic procedures.<sup>178–180</sup>

Calculation of IOL power in cataract surgery is based on the measurements of corneal power/radius of curvature, axial length, and estimation of postoperative anterior chamber depth (effective lens position, ELP).

The main reason for underestimation of IOL power after refractive corneal surgery lies in the inaccurate determination of keratometric power.<sup>181</sup> The keratometer is inaccurate in this setting, because it measures only four points of the cornea in a paracentral region, ignoring flatter (after myopic refractive surgery) or steeper (after hyperopic refractive surgery) more central regions.<sup>182</sup> Computerized videokeratography (CVK) overcomes some of these limitations. However, both keratometry and CVK are inaccurate in eyes that have had myopic PRK or LASIK, because the standardized value for the corneal index of refraction (1.3375) used in both devices is not valid for measuring these corneas.<sup>180,183,184</sup> A second important factor accounting for inaccuracies when using conventional IOL calculations is the ELP, or predicted position of the IOL along the axial length of the eye.

Because preoperative data frequently are not available, and performance of IOL calculations can be time consuming using various individual methods, the American Society of Cataract and Refractive Surgery developed an online Internet-based IOL power calculator to assist surgeons with these difficult IOL calculations. A recent study by Wang et al. evaluated the accuracy of various methods of IOL power prediction using this online IOL power calculator after previous myopic LASIK or PRK. Methods using surgically induced change in refraction as well as methods using no previous data gave better results than methods using pre-LASIK/PRK K values.<sup>185</sup>

As with all refractive procedures and because of the possibility of residual refractive errors, it is important that the patient should have realistic expectations and that the desired target refraction be discussed beforehand.

## SUMMARY

LASIK is an extremely useful technique that combines safety, rapid visual recovery, and flexibility in its ability to be enhanced or combined with other procedures. As the techniques continue to improve, with newer advances in femtosecond and excimer lasers, refractive surgery will continue to evolve and will change the way we assess our refractive expectations and outcomes.

**Definition:** Small incision lenticule extraction (SMILE) is a laser refractive procedure in which a corneal stromal lenticule is created with a femtosecond laser and removed through a small incision in order to correct the refractive error.

## Key Features

- SMILE preserves the corneal integrity better than laser-assisted in situ keratomileusis (LASIK) with its flap-free design eliminating risk of microfolds and flap dislocation.
- Perioperative complications include epithelial abrasions, suction loss during femtosecond laser application, and minor tears of the lenticule or incision edges during lenticule removal.
- Corneal haze is the most common early postoperative complication.
- Early dry eye symptoms can occur, although it spares the subbasal nerve density better than flap-based LASIK, with faster sensitivity recovery.
- Enhancements can be performed with the CIRCLE procedure, where the cap is converted to a flap and followed by excimer ablation of the stromal bed or with surface ablation.

## INTRODUCTION

Over the past decade, femtosecond laser-assisted in situ keratomileusis (FS-LASIK) has become a well-established technique for correcting myopic refractive errors. Femtosecond laser technology allows a more reproducible corneal flap of predetermined thickness, compared with microkeratome.<sup>1</sup> Femtosecond lenticule extraction (FLEX) was later introduced as an alternative to FS-LASIK after development of the VisuMax femtosecond laser (Carl Zeiss Meditec, Jena, Germany). FLEX still required a corneal flap to enter the corneal stroma, as with LASIK. However, FLEX allowed corneal tissue removal by creating a stromal lenticule instead of laser ablation. It proved beneficial to further improve on this and develop a laser refractive technique that did not require use of a corneal flap, minimizing the trauma on the corneal surface and removing the risk of microfolds or flap dislocation.<sup>2,3</sup>

Small incision lenticule extraction (SMILE) was introduced as a next-generation stromal lenticule refractive procedure, further optimizing FLEX.<sup>4,5</sup> As a flap-free technique, an intrastromal lenticule was cut by a femtosecond laser and removed through a small corneal incision. With use of only a small incision (2–4 mm in width) for removal of the lenticule, the corneal integrity was left almost intact.

## FEMTOSECOND LASER SYSTEM

The femtosecond laser ( $10^{-15}$  seconds) that is used for SMILE is a Nd:YAG solid-state laser that emits energy into a focal point with a 1043 nm wavelength and has been discussed in previous sections in this chapter.

## TREATMENT RANGE FOR SMILE

SMILE with VisuMax is approved outside the United States for myopia up to –10.00 diopters (D) in sphere and up to 5.00 D of cylindrical component. SMILE for myopia and astigmatism with VisuMax was Conformité Européenne (CE) marked in 2009. In 2016, the US Food and Drug Administration (FDA) approved VisuMax for myopia from –1.00 D and up to –8.00 D in sphere and astigmatism of 0.50 D or less. Patients with more than –10.00 D in sphere still remain a surgical challenge. For now, VisuMax does not have an approved algorithm for treating hyperopia. Initial studies have tested an improved lenticule shape that removes more tissue in the midperiphery than in the center. Although the technique is promising, it still needs refinement to be on par with the state-of-the-art excimer laser treatments for low to moderate hyperopia.<sup>8–10</sup>

## PATIENT EVALUATION

Patients referred to SMILE should preferably be 18 years or older with a stable refraction for more than 2 years. Standard preoperative evaluation includes uncorrected and corrected distance visual acuity, pupil size, tonometry, pachymetry, tomography, slit-lamp examination, and dilated funduscopy. Tomographic measurements of the corneal front and back curvature should be carefully examined to exclude irregular tomographic patterns or subclinical keratoconus. The patient should not wear contact lenses 2 days (soft lenses) or 2 weeks (hard lenses) before tomographic evaluation. Contraindications for SMILE include corneal scars, corneal dystrophies, and severe dry eyes. Very anxious patients may not be candidates for SMILE, due to the increased risk of perioperative suction loss. LASIK is still the chosen technique to achieve monovision in presbyopic patients, as they often require surgical enhancements, which are done more easily after a flap-based procedure.<sup>11</sup> SMILE may be preferred over LASIK in patients who are involved in contact sports or perform jobs with increased risk of eye trauma, because there is no risk of traumatic flap displacement or dislodgement. Studies suggest that SMILE may also be the best option for moderate to high myopic correction due to higher predictability than after LASIK.<sup>12</sup>

## SURGICAL PROCEDURE

SMILE can be performed under topical anesthesia. Bilateral sequential treatment is usually performed. The patient is positioned supine under the femtosecond laser, and the untreated eye is covered and taped to prevent corneal dehydration. Two drops of 0.8% oxybuprocaine tetrachloride are applied 5 minutes before operation and again just before the lid speculum is installed. A contact glass interface that consists of a peripheral ring of small suction ports is attached to the femtosecond laser. The curved contact glass ensures precise contact to the corneal surface during laser application and is available in various sizes (S, M, L, and type KP). The size of the contact glass should correspond to the white-to-white distance of the patient. A small (S)-sized contact glass is generally preferred, especially in Asian patients with small white-to-white distances. The patient is positioned under the laser head. It is important to dry the ocular surface, especially the inferior fornix, with a sponge to remove any excess tear fluid or ocular surface secretions. This can be performed by placing a disposable sponge in the inferior fornix while the patient is being aligned to the interface cone. Some surgeons advocate the use of a speculum with a

suction device to remove excess tear fluid. Once the patient is under the laser head, the bed is elevated to allow contact with the interface and the anterior corneal surface. Before contact the patient is asked to fixate on a green light from the femtosecond laser for accurate centration. The bed then is elevated further to allow complete contact with the corneal surface. The degree of contact with the ocular surface can be ascertained by the spread of the tear fluid meniscus. In most cases when the tear fluid has spread to three quarters of the width of the cornea, suction is applied. Following suction, the patient is still able to fixate on the green light due to a low intraocular pressure rise.<sup>13,14</sup> Good centration is important because no built-in tracker exists.<sup>15</sup> Patients who have high astigmatism treatments should be marked in the horizontal axis on the slit lamp before the laser procedure. Once under the interface and suction applied, the interface can be rotated to ensure that the marked horizontal axis on the eye is in alignment with that of the horizontal meridian through the right eyepiece in the microscope of the laser, to counter any cyclotorsion.<sup>14</sup>

## Femtosecond Laser Application

SMILE is performed with four sequential laser cuts to create a corneal lenticule and a tunnel incision<sup>4</sup>: (1) a posterior lenticule surface cut in a spiral-in pattern (refractive cut), (2) a vertical cut along the circumference of the lenticule, (3) an anterior lenticule surface cut in a spiral-out pattern (corneal cap), and (4) a superiorly placed 2–4 mm tunnel vertical incision cut that gives access to the lenticule from the corneal surface (Fig. 3.5.1). We prefer to rotate the incision to the superior temporal side in the right eye and superior nasal in the left eye to ease the access for a right-handed surgeon and to avoid any superior pannus and intraoperative bleeding, which maybe be common in patients who wear contact lenses.

The spiral-in pattern of the posterior lenticule cut maximizes the time the patient can focus on the fixation target and minimizes the risk of suction loss due to eye movements. Cutting the posterior surface first ensures that the gas bubbles do not block the laser application of the anterior surface cut. The spiral-in and spiral-out laser firing sequence has also been shown to cause minimal disruption to the collagen lamellae.<sup>7</sup> The laser refractive application takes approximately 20–25 seconds depending on the laser settings. Suction is released automatically after treatment.

The following laser settings can be altered by the surgeon and to determine the lenticule thickness and treatment zone. For the lenticule: lenticule diameter, minimum lenticule thickness, and lenticule side cut angle. For the corneal cap: cap thickness, cap diameter, incision position, incision width, and incision side cut angle. The laser settings are determined by the preoperative refractive status, together with the preference and experience of the surgeon. Surgeons starting with SMILE should perform cases with lenticule thickness of above 70  $\mu\text{m}$  (minimum lenticule thickness of 15  $\mu\text{m}$ ) because it will be easier to perform the removal.<sup>16</sup> Surgeons with more experience with the procedure may perform treatments of  $-1$  D.

## Lenticule Removal

See clip:  
3.5.1

Lenticule removal includes several key stages (Fig. 3.5.2) (Video 3.5.1). The eye can be fixated with a pair of forceps to avoid sudden eye movements during the intrastromal maneuvers. The incision is opened with a Sinskey hook. The two lenticule planes are identified in each corner of the incision. The remaining tissue bridges of the upper surface are broken with a blunt spatula and the lenticule is separated from the cap. The blunt spatula should be gently maneuvered over the lenticule with no major resistance from the remaining tissue bridges. A gentle sweeping movement is advocated ensuring that the dissection passes over the complete area of the anterior surface of the lenticule. The same maneuver is performed on the posterior surface of the lenticule. The lenticule then can be removed through the incision using a pair of forceps. Some surgeons flush the intrastromal pocket with balanced salt solution to remove remaining debris and minimize the risk of epithelial ingrowth. However, the fluid may possibly induce small fluid pockets in the interface and can delay the immediate visual recovery.<sup>17</sup> After lenticule removal, the cap can be massaged with a sponge to remove residual tension folds to the periphery, to minimize irregularities and microfolds on the visual axis when correcting highly myopic patients.<sup>18,19</sup> One drop of fluoroquinolone and corticosteroid are then applied at the end of the procedure.

## Postoperative Management

A postoperative regimen may include a combination of topical dexamethasone and antibiotics, typically 4 times a day for 2 weeks, then tapered to

twice a day for 2 weeks.<sup>16</sup> The patient should use lubricating drops hourly for the first week to ease the discomfort in the postoperative period. Daily activities can be performed, but the patient should avoid swimming pools and extensive eye rubbing during the first 2 weeks. Slit-lamp examination should be performed 1 day, 1 week, and 1 and 3 months after the operation. We normally assess refractive outcome with formal refraction at 1 and 3 months.

## COMPLICATIONS

SMILE has an advantage over LASIK; flap dislocation and detachment are not seen because of the flap-free approach. Nevertheless, specific complications related to the lenticule cutting and removal do occur. Before operation, the surgeon should be aware of how to avoid and manage the most frequent peri- and postoperative complications (Table 3.5.1).<sup>20</sup>

### Perioperative Complications

*Epithelial abrasions* (5.2%) are the most common complication after SMILE but rarely cause sequelae. Central abrasions (0.2%) can be treated with a bandage lens for few days. Epithelial abrasions have been associated with an increased risk of postoperative interface inflammation. Intensive treatment with topical dexamethasone every hour eases the inflammation.<sup>21,22</sup> Incisional abrasions may be seen more commonly in older patients (e.g., in their 40s).

*Minor and major tears* (1.8%) of the lenticule or incision edges are a common complication after SMILE and depend on the width of the incision (Fig. 3.5.3A). Small tears will normally heal with minor scar formations outside the optical zone. Nevertheless, they should be avoided to reduce the risk of postoperative epithelial ingrowth. The incision width should be altered depending on the surgeon's experience, usually 2–3 mm for experienced surgeons but up to 5 mm for inexperienced. Minor tears in the lenticule edge most commonly occur in thin lenticules and after uneven laser application (opaque bubbles or “black areas” where energy was not transferred to the stromal tissue due to opacities).

*Lenticule extraction difficulties* (1.6%) may occur after inadequate laser cutting and/or dissection. Difficulties with lenticule removal may increase the risk of tearing the lenticule, with lenticule tags left in the stromal pocket (0.04%) leading to induced postoperative irregular astigmatism. In those cases, the original incision may be used to remove the lenticule tag.<sup>23</sup> Adequate dissection to remove any remaining stromal bridges anterior and posterior to the optical zone (see earlier) can avoid this complication. The most common reason that may lead to difficulty with removal of the lenticule occurs when the dissection is performed inadvertently on the posterior surface first. This pushes the anterior surface of the lenticule up against the cap, which if unrecognized can cause difficulties in removal. This is particularly common when performing corrections for low myopia. Adequate delineation of the anterior and posterior surfaces of the lenticule at the beginning of the procedure—and custom-made instruments that allow removal of the lenticule from the posterior surface—can help in this situation.<sup>24</sup> Prolonged stromal manipulation may lead to delayed postoperative visual quality.

*Intraoperative suction loss* (1%) with detachment of the contact glass may occur at any time throughout the procedure and will automatically terminate laser application. Common reasons for suction loss include eye squeezing or head movements, often seen in anxious patients, or excess tearing on the ocular surface.<sup>20,21,25,26</sup> Detailed counseling of what visually to expect during the laser application are important. Hence, the surgeon's experience with the technique and patients' counseling may decrease the risk of suction loss.<sup>27</sup> Increased tear production or local anesthesia can induce fluid ingress and detachment between the contact glass and cornea. Small palpebral apertures and a large cap diameter also increase the risk of suction loss.<sup>26,27</sup>

If suction loss occurs before completion of the posterior surface, the surgeon will not be allowed to complete the SMILE procedure, but is given the option to convert to FS-LASIK. The option then is to convert to FS-LASIK. Retreatment can be performed after a few minutes or postponed to another day. If suction loss appears after completing the vertical lenticule side cut, the surgeon can aim to redock and complete the procedure. However, it can be problematic to achieve the exact alignment because of the gas bubble layer obscuring the pupil. Gentle compression on the ocular surface with a wet sponge will allow dispersion of the cavitation bubbles and improve visualization for the patient. Increasing the anterior cap diameter following suction loss will help ensure adequate alignment during redocking to repeat the anterior cut. In a study of suction loss

**Fig. 3.5.1 Laser Firing Sequence.** (A) Fixation during infrared illumination. The patient is instructed to look at the green fixation light before suction is applied. (B) Posterior lenticule surface cut in a spiral in pattern. (C) Lenticule edge cut. (D) Anterior lenticule surface cut in a spiral out pattern. (E) Incision cut.

and redocking during SMILE, uncorrected distance visual acuity (UDVA) was 20/30 or better in 73% of the patients after 3 months (mean preoperative sphere of  $-5.81$  D and cylinder up to  $1.09$  D).<sup>25</sup> In a paired-eyed case study of 35 patients with suction loss in one eye, corrected distance visual acuity (CDVA) was significantly worse after 1 week in the complicated eye but with no significant differences in UDVA and CDVA after 3 months.<sup>21</sup>

## Postoperative Complications

**Corneal haze** (5.6%) is a well-known early postoperative complication after almost all laser refractive procedures and is associated with corneal keratocyte apoptosis and wound healing.<sup>28,29</sup> The corneal haze usually decreases over time. In cases with moderate corneal haze, CDVA had normalized within 2 years after the operation.<sup>21</sup>

(C) Demarcation of posterior lenticule surface. (D) Dissection of the anterior surface. (E) Dissection of the posterior surface. (F) Peripheral dissection of posterior lenticule surface. (G) Dissection of the edge, ensuring the lenticule is detached. (H) Removal of the lenticule with a pair of forceps.

*Continued*

Fig. 3.5.2, cont'd

**Fig. 3.5.3** (A) Minor tear at the incision edge are a common complication after SMILE. Usually, they will heal with minor scar formations and no influence on the visual outcome. Nevertheless, they should be avoided due to increased risk of epithelial ingrowth. (B) Epithelial ingrowth 6 weeks after operation due to seeding of epithelial cells through the incision. The epithelial ingrowth was left untouched because it was located outside the visual axis and the patient did not have any visual complaints. (Courtesy Dr. C Chan.)

TABLE 3.5.1 Incidence of Peri- and Postoperative Complications Following SMILE.	
Perioperative Complications	Postoperative Complications
Peripheral (5.2%) and central (0.2%) epithelial abrasions	Corneal haze/nontransparency (5.6%)
Minor and major tears (1.8%)	Dry corneal surface, day 1 (3.2%)
Lenticule extraction difficulties (1.6%)	Epithelial ingrowth (0.5%)
Suction loss (1%)	Irregular corneal topography (0.5%)
Fiber in interface (0.2%)	Visually insignificant microstriae (0.4%)
Remaining lenticule remnant (0.04%)	Diffuse lamellar keratitis (0.2%)
	Monocular ghost images (0.2%)

Early dry eyes (3.2%) at day 1 may be seen in combination with corneal haze. In several studies, the flap-free approach has been shown to preserve the subbasal nerve layer density better after SMILE compared with FS-LASIK in both short- and longer-term studies.<sup>30–32</sup> Corneal sensitivity recovery has been shown to be faster after SMILE. However, early postoperative dry eye symptoms are comparable with flap-based procedures.<sup>30,33</sup> Tear break-up time (TBUT), Schirmer’s test, and tear meniscus height were similar after SMILE and FLEX up to 6 months after operation in a contralateral eye study.<sup>30</sup>

Epithelial ingrowth (0.5%) is seen when epithelial cells proliferate at the incision site or are displaced into the interface during lenticule removal (Fig. 3.5.3B). Epithelial ingrowth to the interface is more rarely seen after SMILE than after LASIK. Epithelial islands may be spotted at the incision site, often in relation to a minor tear after lenticule removal difficulties.

The epithelial islands may be left alone if no progression is observed. They also can be scraped off the border of the incision using a pocket epithelial remover or treated with Nd:YAG laser. Only in very severe cases with epithelial ingrowth to the interface center does it become visually significant.<sup>34</sup> In such situations if the epithelium cannot be removed through the small incision, an alternative option would be to perform a conversion of the pocket to a flap to allow a more extensive irrigation of the stromal interface.

Diffuse lamellar keratitis (DLK) (0.2%), also known as Sands of Sahara or interface inflammation, typically appears after 1–3 days, accompanied by decreased visual acuity, pain, and photophobia.<sup>35</sup> High laser energy settings during photodisruption increase the risk of diffuse lamellar keratitis.<sup>36</sup> Thin stromal lenticules may increase the risk of DLK, because gas bubbles after photodisruption accumulate within a small stromal area and provoke a strong inflammatory response.<sup>35</sup> DLK is frequently reported in conjunction with central aberrations and postoperative epithelial defects.<sup>21</sup> DLK may be successfully treated with topical corticosteroids or flushing the interface in some cases. In rare cases, a bacterial or fungal organism can be the cause of the inflammation and should always be considered if the patient does not respond to the treatment.<sup>37</sup> From the authors’ experience a higher incidence of DLK has been reported when the interface has not been irrigated following the procedure.

HIGHER-ORDER ABERRATIONS

Increased postoperative higher-order aberrations (HOAs) may promote visual complaints such as glare, halos, reduced contrast sensitivity, and poor night vision.

Preoperative patient evaluation includes pupil size and should be taken into consideration when the lenticule diameter is determined for the operation. Patients with large pupils may be more troubled by postoperative spherical aberrations if a small lenticule diameter is chosen. In particular, spherical aberrations may induce halos and decreased night vision due to the myopic shift with a large pupil (night myopia). However, a large lenticule diameter requires a thick lenticule to gain the same amount of correction and may not be acceptable when correcting highly myopic patients. Coma may increase after decentered laser treatment and can lead to symptoms of halos and monocular diplopia. In contrast to state-of-the-art excimer lasers, the VisuMax laser lacks an eye-tracking system. The alignment relies on the patient's cooperation and the surgeon's objective adjustment. Nevertheless, VisuMax is on par with the MEL 90 laser used for LASIK when it comes to centration during surgery.<sup>38,39</sup> Studies have reported an increase in coma and HOAs but not in spherical aberrations after SMILE.<sup>40–44</sup> A minor decrease is seen years after the operation, probably explained by remodeling of the epithelial layer.<sup>45</sup> Corneal aberrations after SMILE have been shown to be less than after FS-LASIK,<sup>42–44</sup> although one study reported a similar shift in aberrations after SMILE and LASIK.<sup>46</sup>

## BIOMECHANICAL STABILITY

In contrast to a flap-based LASIK procedure, SMILE involves the creation of a cap. Thus SMILE may be able to better preserve the corneal tectonic integrity because the small incision leaves most of the anterior corneal collagen intact. Most of the corneal strength is located in the anterior third of the cornea and is crucial to withstand the intraocular pressure.<sup>47</sup> From earlier ex vivo studies of the depth-dependent tensile strength, Reinsteint et al.<sup>48</sup> developed a mathematical model to predict the tensile strength following SMILE, LASIK, and photorefractive keratectomy (PRK). The model demonstrated greater postoperative tensile strength after SMILE than after LASIK and PRK, due to the creation of the corneal cap. Several studies have assessed the postoperative corneal biomechanical properties in vivo after SMILE and LASIK by using the Ocular Response Analyzer and Corvis ST (Scheimpflug-based tonometry). In a randomized pair-eyed study of SMILE and LASIK, both corneal hysteresis (CH) and corneal resistance factor (CRF) decreased after operation, but with no significant differences between the two methods.<sup>49</sup> Likewise, a randomized pair-eyed study of SMILE and FLEX reported no significant differences in terms of CH and CRF between the two methods after 6 months.<sup>50</sup> For now, no studies have performed a randomized pair-eyed study with Corvis ST. Retrospective studies using the Corvis ST on LASIK, FLEX, and SMILE reported similar reduction in the corneal biomechanical properties with regard to the deformation pattern during the airpuls.<sup>51,52</sup>

Iatrogenic ectasia with corneal protrusion and decreased visual acuity is a rare but severe complication after LASIK (0.05%).<sup>53</sup> The general recommendation for preventing ectasia is a minimum residual bed thickness of 300  $\mu\text{m}$  in LASIK. The use of the same recommendations in SMILE has been a topic of discussion because the cornea may be more biomechanically robust with less risk of iatrogenic ectasia.<sup>48</sup> Nevertheless, a few cases of iatrogenic ectasia have been reported after SMILE, although the preoperative evaluation of the patients may have shown abnormal preoperative topographical patterns.<sup>54–58</sup>

## REFRACTIVE AND VISUAL OUTCOME

SMILE has shown to be comparable with LASIK in terms of efficacy, predictability, stability, and safety.<sup>21,42,43,59,60</sup> However, the learning curve of SMILE is likely to affect the postoperative results in the early phase.<sup>6,27,60</sup> This can possibly be avoided with proper supervised training and earlier experience with corneal surgery.<sup>61</sup> In a study of SMILE for low myopia (mean spherical equivalent [SE] of  $-2.61$  D and cylinder up to  $1.50$  D), UDVA was 20/20 or better in 96% of the patients after 1 year.<sup>62</sup> In terms of CDVA, 9% lost one Snellen line but no eyes more than two. Postoperative SE was within  $\pm 0.50$  D and  $\pm 1.00$  D in 84% and 89%, respectively. Minor regression was reported from 3 to 12 months, where SE changed more than  $0.5$  D in 8% of the patients. A study of SMILE for moderate to high myopia (mean SE of  $-7.18$  D and cylinder up to  $1.50$  D), UDVA was 20/40 or better in 97% of the patients after 3 months.<sup>6</sup> CDVA improved slightly but significantly from baseline to 3 months, and with 2.4% loss in CDVA of two Snellen lines or more. In eyes with emmetropia as target refraction, 80% and 94% were within  $\pm 0.50$  D and  $\pm 1.00$  D, respectively. Studies with up to 5 years of follow-up report stable visual outcomes but a minor myopic regression of  $0.48$  D.<sup>45,63,64</sup> A study of SMILE for astigmatism ( $1.81$  D in mean cylinder, range  $0.75$  D– $4.00$  D) reported an astigmatic undercorrection of 11%

of attempted correction after 12 months.<sup>65,66</sup> Postoperative undercorrection tended to increase with higher attempted astigmatic correction and may be taken into consideration if the surgeon chooses to personalize the nomogram for astigmatic treatments.<sup>67</sup>

## RETREATMENTS

With improvement of the VisuMax nomogram, SMILE has proven to be accurate and predictable for correcting myopia and myopic astigmatism.<sup>5,6,45,68,69</sup> Still there is a risk of postoperative under- or overcorrection, but it does not seem to be related to the intended refractive correction.<sup>6</sup> Furthermore, the minor but significant myopic drift may require further enhancements years after SMILE.<sup>45,63,64</sup> It raises the question of how to correct patients already treated with SMILE. After LASIK or FLEX, the surgeon would simply lift the flap and perform excimer reshaping in the earlier treated zone. Several techniques for postoperative enhancement have been suggested, and the chosen technique should always be based on an extensive evaluation of the postoperative tomography, the degree of correction required, and the visual complaints of the patient.<sup>70</sup>

In the CIRCLE procedure available with VisuMax, the corneal cap can be converted to a flap with use of the previous upper surface and lenticule edge cuts.<sup>71,72</sup> With the femtosecond laser, the surgeon creates a circular incision in relation to the edge of the previous cap and leaves a hinge in the superior position. A lamellar cut connects the new circular cut with the previous SMILE optical zone. Lifting the flap gives access to the stromal bed, where reshaping can be done with excimer laser. The visual and refractive outcomes after the CIRCLE procedure followed by excimer laser surgery have proven to be reliable. Reportedly, 95.8% of patients with emmetropia as target refraction reached a UDVA of 20/20 or better 3 months after the CIRCLE procedure, with a residual refractive error of  $0.10$  D (mean preoperative SE:  $-0.74$  D, range  $-2.98$  D– $0.38$  D).<sup>71</sup> Another technique involves topography-guided PRK in patients with postoperative irregular topography.<sup>73</sup> Corneal haze has been reported after the PRK treatment even after minimal ablation depths. Perioperative mitomycin-C may be beneficial to prevent postoperative haze. In one case study, enhancement was performed with SMILE using the original cap. The laser application was stopped after the new lower surface and lenticule edge was cut, and the new lenticule was removed though the original incision.<sup>74</sup>

## CONCLUSIONS

SMILE has emerged as a new technique for correcting myopia and astigmatism. SMILE preserves the corneal integrity by creating a corneal cap with no risk of flap displacement as may be seen after LASIK and FLEX. Several studies have shown SMILE to have high efficacy, predictability, stability, and safety with fewer postoperative HOAs than after LASIK. In future, the development and refinement of SMILE may open up new ways of correcting hyperopia by removal of a piece of tissue that flattens the corneal curvature. Until then, LASIK and PRK are the recommended corneal treatment for correcting low hyperopia.

# Wavefront-Based Excimer Laser Refractive Surgery

## 3.6

Faisal M. Tobaigy, Daoud S. Fahd, Wallace Chamon

**Definition:** Wavefront-customized excimer laser refractive surgery corrects pre-existing lower- and higher-order aberrations. Wavefront-optimized treatments preserve pre-existing corneal optical aberrations (customizing for spherical aberration).

### Key Features

- Zernike polynomials and Fourier transforms are used to represent and analyze the ocular wavefront.
- Optical properties influence image quality.
- Different devices measure ocular aberrations differently.
- Wavefront-customized and wavefront-optimized ablations result in better visual acuity and mesopic contrast sensitivity.

### INTRODUCTION

The eye is a complex, imperfect optical system. As light rays from distant objects pass through the optical components of the eye, they refract at the tear film and at corneal and crystalline lens interfaces. Any deviation from a perfectly focused optical system is referred to as aberration. Most of these aberrations reflect myopia, or hyperopia, and regular astigmatism, known as lower-order aberrations (LOA), which can be corrected with spherocylindrical spectacles.<sup>1</sup> Other optical aberrations are commonly referred to as irregular astigmatism and include spherical aberration, coma, trefoils, and quadrifolds. Irregular astigmatism encompasses higher order aberrations (HOA).

HOA may decrease the quality of vision and cause symptoms in up to 15% of the general population.<sup>2</sup> Rigid contact lenses can correct HOA that are generated at the anterior corneal surface. More advanced treatments involve the use of a personalized wavefront-guided laser refractive technique to reshape the surface of the cornea that leads to a more optically desired outcome.<sup>1</sup>

A customized corneal shaping requires wavefront analysis of the eye (aberrometry). For reproducibility, the waveform can be decomposed into components, using either Zernike polynomials or Fourier analysis.<sup>3-5</sup> The wavefront map is digitally interfaced with an excimer laser to control the delivery of a laser beam across the cornea in a customized fashion.

In the majority of the population, other noncustomized treatments may use epidemiological data to predefine ablation profiles that may be suitable to improve high-order aberration, especially spherical aberration. Although these treatments are not personalized for each patient, they are based on epidemiological information of wavefront analyses and are commonly known as wavefront optimized treatments.<sup>6</sup>

### WAVEFRONT OPTICS

The wavefront is the locus of points in an optical pathway having the same phase. If all incoming rays are parallel, and the eye is free from any aberrations, the resultant emerging wavefront is a perfectly flat surface. In other words, all light rays coming from a point source located at infinity focus at a single point on the retina. In reality, though, the focusing properties of a real eye are not completely uniform: Some areas bend light more strongly than others. The wavefront aberration is the deviation of a particular eye's wavefront from the ideal wavefront in the pupillary plane. Its magnitude is

entirely dependent on the diameter of the pupil; a larger diameter leads to a larger wavefront error (Fig. 3.6.1).<sup>4,7,8</sup>

### HIGHER-ORDER ABERRATIONS

HOA are monochromatic refractive disorders that may limit the vision of healthy eyes to less than the retinal detection threshold. HOA cannot be corrected with spherocylindrical lenses or with standard refractive surgery.<sup>5,8</sup> They have been categorized using Zernike polynomials by radial order and by angular frequency, with third order and higher constituting HOA.<sup>5</sup> The higher the order, the less visually significant the aberration. The two most frequently discussed aberrations are spherical aberration (which causes halos and night vision disturbances) and coma (which is associated with monocular diplopia).<sup>4,9</sup> The wavefront in spherical aberration is spherical in the center of the pupil but changes its curvature toward the edge of the pupil, giving concentric rings of focus that result in point images with halos. In coma, the wavefront is asymmetrical, producing a comet-shaped pattern (Fig. 3.6.2). Trefoil, quadrifoil, pentafoil, and secondary astigmatism are other HOA (see Fig. 3.6.2).

### IDEAL CORNEAL SHAPE

The shape of the cornea is prolate (more curved in the center) to allow for a lower total HOA.<sup>10</sup> The Q-value of the central cornea (5–7 mm) in a normal population varies from –0.21 to –0.27, meaning that the central cornea has a stronger curvature than the periphery.<sup>11</sup> This aspherical shape allows for focusing of rays coming from the periphery and those coming from the center on one point, correcting for inherent spherical aberration of spherical lenses. Any change in the average prolate corneal shape toward a more oblate profile (less curved in its center) leads to induction of spherical aberrations and consequently a decrease in night vision and contrast sensitivity.

### MEASUREMENTS OF WAVEFRONT ABERRATIONS

Zernike polynomials and Fourier transforms are used to analyze the detected ocular wavefront.<sup>5,12</sup> Zernike polynomials are a sequence of polynomials based on a radial model, whereas Fourier transforms represent nonradial mathematical functions of frequency. Most aberrometers used for customized laser surgery rely on Zernike polynomials to decompose the wavefront aberrations (Fig. 3.6.2). They can, in principle, measure an infinite number of aberration orders. Clinically, data up to the Zernike fifth order capture nearly all the aberration variance typically found in normal human eyes.<sup>7,8</sup> The Fourier analysis can decompose an image into spatial frequency components with a higher resolution of the surface (Fig. 3.6.3).

The measured wavefront errors are represented as root mean square deviations (RMS), which are correlated to the absolute deviation of an ideal wavefront. Applegate and colleagues<sup>4,5</sup> evaluated the effect of individual Zernike modes on visual quality and noted large differences in their subjective impact, with those in the middle of a given Zernike order influencing vision more than those at the periphery. For example, in the second radial order, defocus degrades vision more than astigmatism. Similarly, in the third and fourth order, coma and spherical aberration degrade vision more than trefoil and quadrifoil, respectively (see Fig. 3.6.2).

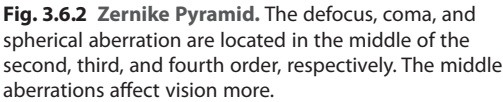

**Fig. 3.6.1 Aberrations of the Eye With Different Pupil Sizes.** (A) In an ideal eye with no ocular aberrations, a point source of light focuses on the retina. Image quality is not influenced by pupil size. (B) In an eye with an error of refraction (here with axial myopia), pupil size plays an important role in image quality. Rays striking the cornea further away from the center are bent differently from those striking the corneal center due to the intrinsic corneal shape. The formed aberrated wavefront is greater in the dilated eye compared with the miotic eye.

## QUALITY OF VISION AND MEASURES OF OPTICAL QUALITY

Visual assessment has two parts, acuity (quantity) and quality. A good visual acuity can be achieved on a high-contrast eye chart by correcting LOA using the standard refractive ablation. Vision quality refers to all fine details, colors, and shades of images after they are in focus—it is especially compromised in dim light. It can manifest as double vision, ghosting, glare, halos, starbursts, and reduced contrast sensitivity.

Standard approaches to quantification of the optical quality of the eye describe either the optical properties of the eye (aberration maps, wavefront error maps) or the effect these properties have on image quality (abnormality of an image of a point light source or of a sinusoidal grating).<sup>13</sup>

Aberration maps measure the undulating wavefront from an aberrated eye at the pupillary plane; they are quantified by the RMS wavefront error. Despite the fact that RMS wavefront error is not a good predictor of the subjective impact of aberrations on vision, it usually gives a rough estimate of the overall aberrations of the eye.<sup>10,13,14</sup>

to the image is called the modulation transfer function (MTF) and phase transfer function (PTF), respectively. The eye's OTF includes both the MTF and PTF.<sup>13,14</sup>

Several methods for assessing the wavefront aberrations in human eyes are currently available. Each method has its own way of measuring the

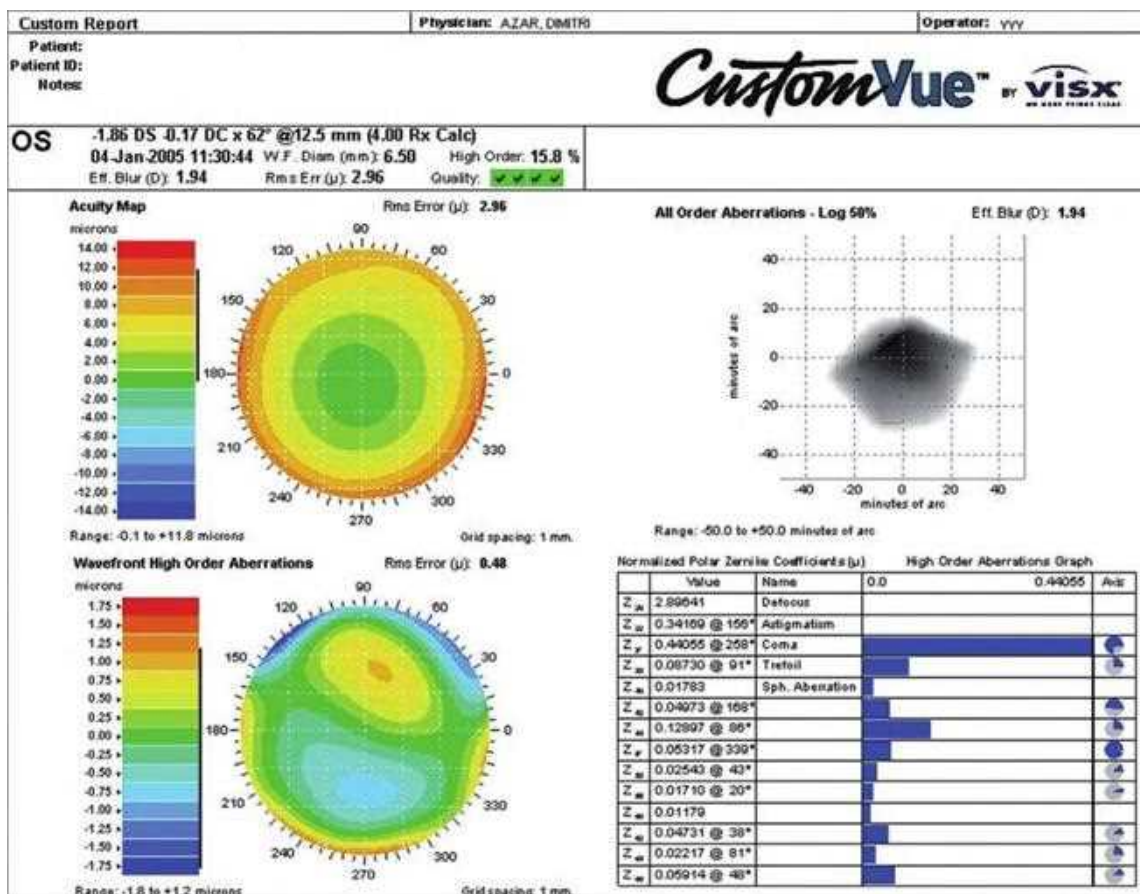

Fig. 3.6.4 VISX WaveScan Map Showing a High Amount of Coma.

displacement of a ray of light from its ideal position. They can be generally classified as outgoing or ingoing aberrometers.

Devices based on the Hartmann–Shack principle are currently the most widely used. These devices analyze an outgoing light that emerges or is returned from the retina and passes through the optical system of the eye.<sup>15,16</sup> A narrow beam of light is projected onto the retina, and its image passes through the lens and the cornea and exits the eye. The Hartmann–Shack sensor has a lenslet array that consists of a matrix of small lenses.<sup>15,16</sup> The light that emerges from the eye is focused on a charge-coupled device (CCD) camera through each lenslet to form a spot pattern. The spot pattern of an ideal subject with a perfect wavefront will be exactly the same pattern as the reference grid; a distorted wavefront will create an irregular spot pattern. Displacement of lenslet images from their reference position is used to calculate the shape of the wavefront. The advantages of this system include the fact that it measures wavefront in one shot; hence it is faster, leading to a higher resolution and a higher repeatability (Figs. 3.6.4 and 3.6.5).

Tscherning aberrometry analyzes the ingoing light that forms an image on the retina.<sup>17</sup> A grid pattern formed by multiple spots is projected through the optical system of the eye and forms an image on the retina. This image is observed, evaluated, and captured on a CCD similar to a fundus camera. The distortion of the grid pattern enables calculation of the aberrations of the optical system of the eye.<sup>17</sup>

Ray-tracing aberrometry measures ingoing light that passes through the optical system of the eye and forms an image on the retina.<sup>17</sup> It measures rays sequentially making it much slower (the total time of scanning is 10–40 milliseconds) and decreasing its precision. The iTrace aberrometer (Tracey Technologies, Houston, TX) is the only one based on the retinal ray-tracing technology and is not currently linked to any customized laser platform.<sup>18</sup>

The scanning slit refractometer is a double-pass aberrometer (slit skioscopy) that is based on retinoscopic principles.<sup>19</sup> Both the projecting system—consisting of an infrared light source—and the receiving system rotate at high speed around the optical axis synchronously, with 360° meridians measured in 0.4 seconds. A group of photodetectors is located above and below the optical axis at 2.0, 3.2, 4.4, and 5.5 mm, and they detect the time needed for reflected light to reach them. The time difference depends on the type and amount of refractive error and is converted into the refractive power.<sup>19</sup> This principle is used in the ARK 10000 Optical Path Difference Scanning System (OPD-Scan) distributed by Nidek.

## WAVEFRONT-BASED SURGERY

The aim of wavefront custom ablation, in addition to spherocylindrical correction, is to adjust for the pre-existing aberrations and those that may be induced by conventional laser vision correction.<sup>20,21</sup> To achieve this aim, preoperative ocular higher-order aberration wavefront measurements should be accurate, and the laser ablation profiles should be precise—hence efficient eye-registration and tracking devices, a small laser spot size, and a sufficient corneal bed thickness become paramount for achieving superior clinical results.

Wavefront measurements should be accurate; the alignment of the line of sight is important to avoid artifacts. Common clinical conditions, such as tear film abnormalities or opacities, may present challenges to wavefront measurements.<sup>15</sup> Eyes with small-diameter pupils may be difficult to measure and provide information beyond the 3-mm optical zone and therefore require pharmacological dilatation. However, some variations in the wavefront maps have been seen with some pharmaceutical agents. It has been reported that cyclopentolate eyedrops lead to a significant difference in the preoperative refractive error wavefront compared with the subjective refraction, whereas Neo-Synephrine does not significantly influence measurements.<sup>22</sup> An eye with marked aberrations such as scars or keratoconus may be difficult to measure because of complete light scatter and the inability of the source testing light to reach to the retina and reflect back to the CCD camera.<sup>15</sup>

The algorithm for converting measurements into an ablation profile should be faithful to the original maps. It should be optimized to provide the best optical quality over the optical zone and tapering of the ablation in the surrounding zone (Figs. 3.6.6 and 3.6.7).

Another important issue for successful custom ablation surgery is eye registration and eye tracking during corneal laser ablation. The wavefront data must be transferred to the laser machine and applied to the same location on the eye from which they were captured. A small misalignment in the axis can have significant impact on the results of the procedure. It may actually cause new HOA due to misalignment of the pattern of treatment to the actual wavefront error on the eye. It is common to have 5°–7° of cyclotorsion when changing from sitting position to supine position. It has been reported that 50% of the visual benefit correction of HOA is lost with a 250 μm decentration or a 10° eye rotation.<sup>23</sup> Ideally the wavefront must be centered and registered with respect to a fixed ocular structure to avoid misalignment between the captured wavefront and the delivered laser. No

confusion should exist regarding axis alignment of wavefront-based treatments. Considering that they are based on a detailed map of the entrance pupil, centration of the treatment is unquestionably done over the pupil. All concerns about kappa angle or centration on different axes only apply to noncustomized treatments.

Two main methods of using wavefront information in refractive surgery are wavefront-optimized ablation and wavefront-customized ablation. Wavefront-optimized ablation aims at preserving the eye's pre-existing optical aberrations using adjustments based on population averages and at optimizing the asphericity of the cornea. The ablation profile is based on an ideal model without evaluating the patient's own aberrometry, therefore it is not a customized treatment. Wavefront-customized ablation leads to having an individual treatment ablation profile based on the patient's own aberrometry; therefore it would be able to correct for pre-existing HOA.

## RESULTS

Sakimoto et al. reviewed the outcomes for wavefront-customized LASIK in low to moderate myopia using three separate laser platforms.<sup>21</sup> The postoperative manifest spherical equivalent (SE) was within  $\pm 1.00$  diopters (D) in 96% of eyes and within  $\pm 0.50$  D in 81%. Ninety-eight percent of patients had postoperative uncorrected visual acuities (UCVA) better than 20/40, and 89% had UCVA equal to or better than 20/20. A loss of best spectacle-corrected visual acuity (BSCVA) of more than two lines was seen in 0.5% of patients. Wavefront-customized LASIK seems to be most successful in patients with low myopia: 95% of the patients with  $-2.00$  D or

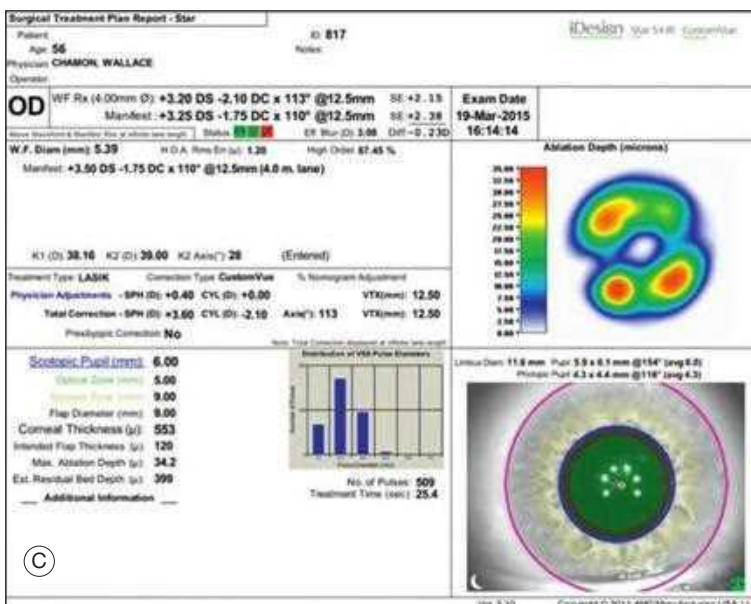

less SE achieved UCVA of 20/20 or better, as did 91% of patients with preoperative SE of  $-2.00$  to  $-4.00$  D. A marked difference in 20/20 or better postoperative UCVA was seen between the wavefront-customized and conventional LASIK treatments. In wavefront LASIK, 89% of myopic patients achieved this level of vision, whereas 72% of patients treated with conventional treatment achieved 20/20 or better. Feng et al. did a meta-analysis comparing 458 eyes with wavefront-customized and 472 eyes with wavefront-optimized LASIK treatments for myopia (SE between  $-0.25$  and  $-9.75$  D).<sup>24</sup> No statistically significant difference was detected in eyes achieving 20/20 UCVA or better, nor in eyes achieving postoperative SE within  $\pm 0.50$  D, nor in the average change in HOA. No eye lost two or more lines of BSCVA.<sup>24</sup>

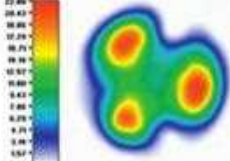

## WAVEFRONT PLATFORMS (TABLE 3.6.1)

## CONCLUSIONS

Knowledge of ocular aberrations can lead to better understanding of the quality of vision. Adequate interpretation of ocular wavefront maps can help in planning for custom LASIK treatment. Our quest for achieving perfect vision following laser vision correction is still ongoing. Despite falling short of the high expectations of supervision with wavefront-guided ablations promised by earlier studies, wavefront-based treatments still shows superiority over conventional treatment profiles.

**Definition:** Phakic intraocular lenses (IOLs) are artificial lenses implanted in the anterior or posterior chamber of the eye to correct refractive errors. They preserve the natural crystalline lens to maintain accommodation.

## Key Features

- Three models of phakic IOLs are described: anterior chamber angle-supported, anterior chamber iris-fixated, and posterior chamber IOLs.
- Improved IOL designs and better preoperative screening are providing increased safety and efficacy for the correction of severe ametropias.

## Associated Features

- Early models of phakic IOLs were made of rigid polymethyl methacrylate (PMMA). Newer lenses are foldable, requiring a smaller incision and providing a faster visual recovery.
- Complications are IOL specific and include over- and undercorrection, glare and halos, endothelial cell loss, glaucoma, pigment dispersion, and cataract formation.
- Surgical peripheral iridectomy or preoperative YAG laser iridectomies are necessary to avoid postoperative pupillary-block glaucoma in most IOL models.

## INTRODUCTION

If high ametropia occurs, laser corneal refractive surgery (photorefractive keratectomy [PRK] and laser-assisted in situ keratomileusis [LASIK]) is limited by decreased safety, predictability, and efficacy of postoperative results. Now a growing interest exists in the use of phakic intraocular lenses (IOLs) to correct these refractive errors. Phakic IOL implantation has the advantage of preserving the architecture of the cornea. Additionally, it may provide more predictable refractive results and better visual quality than surgical techniques that manipulate the corneal curvature.

## HISTORY OF PHAKIC LENSES

Clear lens extraction for the correction of myopia was a concept introduced in the early 1800s, becoming increasingly popular from 1850 to 1900.<sup>1</sup> After the discovery of sterilization in 1889, a rush for myopia correction by clear lens extraction was started by Fukala in Austria/Germany ("Fukala surgery") and Vacher in France.<sup>1</sup> It was not until the end of the nineteenth century, however, that complications of this operation (e.g., retinal detachment and choroidal hemorrhage) began to be reported, and the technique largely fell out of favor.

In the 1950s, an emergence of the idea of correcting myopia by inserting a concave lens into the phakic eye was seen. At this time, Strampelli, Barraquer,<sup>2</sup> and Choyce experimented with anterior chamber (AC) angle-fixed lenses, which they eventually abandoned because of corneal edema, chronic iritis with pupil ovalization, and iris atrophy. In the 1980s

**Fig. 3.7.1** Angle-supported Baikoff ZB5M (left) and the NuVita MA20 (right).

and 1990s several PMMA angle-supported AC phakic IOLs were introduced, but subsequently discontinued due to the same complications. The most important were the Baikoff<sup>3,4</sup> lens, ZB and ZB5M models (Fig. 3.7.1), which were based on the multiflex Kelman anterior chamber IOL and the ZSAL-4 (Morcher GmbH, Stuttgart, Germany).<sup>3,5-9</sup> The ZB5M was later modified to implement thinner optics, greater effective optic diameter, flatter anterior face, and improved loop profile to reduce angle trauma. It was called NuVita MA20 (Bausch & Lomb, Rochester, NY) (see Fig. 3.7.1).

The first iris-fixated lenses were sutured to the iris stroma. The claw fixation method rendered iris stitching unnecessary. Worst introduced his final conceptual model of the midperipheral fixation iris-claw lens for secondary lens implantation. For many years, the iris-claw lens was used as a primary implant after intracapsular and extracapsular cataract extraction because of good tolerance and refractive results; it is still used today as a standby lens in cases of posterior capsule rupture. In 1986 Worst and Fechner<sup>10,11</sup> modified this IOL to a biconcave AC lens for the correction of myopia. To increase the safety of this IOL and minimize the possibility of IOL–cornea contact, the biconcave design was changed in 1991 to a convex–concave model with a lower shoulder, a thinner periphery, and a larger optic diameter (Fig. 3.7.2). This lens was called the Worst myopia claw lens. The name of the lens then was changed to the Artisan–Worst lens (Ophtec BV, Groningen, Netherlands) and Artisan–Verisyse lens (Abbott Medical Optics, Inc., Abbott Park, IL).

In the mid-1980s, the implantation of posterior chamber IOLs in phakic eyes was reported by Fyodorov.<sup>12</sup> The original lens design was a "collar-button" type, with the optic located in the anterior chamber and the haptics behind the iris plane. The design, modified by Chiron-Adatomed to produce a silicone elastomer posterior chamber lens, was reported to have a high incidence of cataract formation.<sup>13</sup> Further modification, the phakic refractive lens (PRL) (Ioltech/CIBA Vision, La Rochelle, France) (Fig. 3.7.3), had a greater vaulting, decreasing the incidence of cataract but causing zonular lesions.<sup>14</sup> Currently, the implantable collamer lens (ICL) (STAAR Surgical Co., Monrovia, CA) is the only posterior chamber phakic IOL available (Fig. 3.7.4).

**Fig. 3.7.2** Iris-fixated Verisyse Lens in situ.

**Fig. 3.7.3** Posterior Chamber Phakic Refractive Lens (PRL) for Myopia (top) and Hyperopia (bottom).

### BOX 3.7.1 General Criteria for Implanting Phakic IOLs

- Age >21 years
- Stable refraction (less than 0.50 D change) for 1 year
- Clear crystalline lens
- Ametropia not suitable/appropriate for excimer laser surgery
- Unsatisfactory vision with/intolerance of contact lenses or spectacles
- Functional and occupational requirements
- Anterior chamber depth (measured from endothelium)\*  
Artisan–Verisyse / Artiflex–Veriflex:  $\geq 2.7$  mm  
ICL:  $\geq 2.8$  mm for myopia,  $\geq 3.0$  mm for hyperopia
- A minimum endothelial cell density of:  
 $\geq 3000$  cells/mm<sup>2</sup> at 21 years of age  
 $\geq 2600$  cells/mm<sup>2</sup> at 31 years of age  
 $\geq 2200$  cells/mm<sup>2</sup> at 41 years of age  
 $\geq 2000$  cells/mm<sup>2</sup> at 45 years of age or more
- No ocular pathology (corneal disorders, iris or pupil anomaly, glaucoma, uveitis, maculopathy, etc.)

\*Güell JL, Morral M, Kook D, Kohnen T. J Cataract Refract Surg. 2010;36:1976–93.

## INDICATIONS OF PHAKIC LENSES

Regardless of the type of phakic IOL, careful patient selection is critical for successful outcomes. General criteria should be followed (Box 3.7.1).

### Moderate and High Myopia

Patients who are poor candidates for laser correction may be candidates for phakic IOL. Food and Drug Administration (FDA)–approved excimer lasers can treat myopia of up to  $-12.00$  diopters (D). However, the higher the intended correction, the thinner and flatter the cornea will be postoperatively. For LASIK surgery, one must preserve a safe residual corneal stromal bed of at least  $250\ \mu\text{m}$ . A more conservative value would be  $300\ \mu\text{m}$  and a percentage of tissue altered (PTA) no more than 40%.<sup>15,16</sup> There is a limit to the amount of central flattening one can induce in the cornea, which is usually around  $35.00$  to  $36.00$  D (final keratometry). Beyond these limits, there is an increased risk of developing corneal ectasia due to thin residual stromal bed and loss of visual quality and night vision problems due to excessive corneal flattening. It was shown that LASIK also induces significant spherical and coma aberrations compared with phakic IOLs for high myopia.<sup>17</sup> Because of these risks, a current trend exists toward reducing the upper limits of LASIK and PRK to around  $-8.00$  to  $-10.00$  D. Above these limits, and in cases of keratoconus or keratoconus-suspect, or the cornea is too thin or too flat for laser surgery, phakic IOLs become the major alternative.

Most phakic IOLs for myopia can correct up to around  $-20.00$  D (Table 3.7.1). In 2004 the FDA approved the first phakic IOL designed to correct high myopia. The Verisyse (AMO/Ophtec, USA Inc.), also known as Artisan–Worst iris-claw lens, was approved for myopia ranging from  $-5.00$  to  $-20.00$  D with astigmatism less than or equal to  $2.50$  D. In 2005 a second phakic IOL was approved by the FDA. The Visian ICL was approved for myopia ranging from  $-3.00$  to  $-20.00$  D with astigmatism less than or equal to  $2.50$  D.

### High Hyperopia

The upper limits for hyperopic laser surgery are around  $+5.00$  to  $+6.00$  D. Higher attempted corrections can cause excessive steepening of the cornea (above  $50.00$  D), usually with a small optical treatment zone, leading to induced aberrations, especially spherical and coma aberrations and degradation of optical quality. Phakic IOLs may be indicated for the correction of hyperopia up to  $+22.00$  D (see Table 3.7.1). In many cases, however, these eyes have insufficient AC depth, limiting its implantation. For hyperopia, refractive lens exchange (refractive lensectomy) with IOL implantation is the main alternative for laser surgery in the presbyopic age group.<sup>18,19</sup>

### High Astigmatism

LASIK is the treatment of choice for astigmatism of up to around  $5.00$ – $7.00$  D. One may consider implanting toric phakic IOLs in cases of high degrees of astigmatism whether associated with myopia or hyperopia (see Table 3.7.1). Both spherical and cylindrical corrections can be combined

TABLE 3.7.1 Current Phakic IOLs, Either FDA Approved or With European Conformity Mark

Type of Lens	Name/Model	Power Range (D)	Optic Size (mm)	Length (mm)	Incision Size (mm)	Material	Manufacturer

AC, Anterior chamber; FDA, Food and Drug Administration; ICL, implantable collamer lens; IOLs, intraocular lenses; PC, posterior chamber, PMMA, polymethyl methacrylate.

Fig. 3.7.5 Toric Artiflex to Correct Residual Myopic Astigmatism After 6-mm Intracorneal Ring Segment Implantation in a Patient With Keratoconus.

in these lenses, which aims to correct the total refractive error, but to date, only spherical corrections are FDA approved. The sum of minus sphere and cylinder cannot exceed −14.50 D with Artiflex toric and −23.00 D with Artisan toric.

With irregular astigmatism or if toric models are not available, astigmatism can be reduced with relaxing procedures such as limbal relaxing incisions, arcuate keratotomy, intrastromal rings<sup>20</sup> (Fig. 3.7.5), and with toric pseudophakic IOLs in cases where the crystalline lens is opaque. LASIK or PRK could be performed after phakic IOLs to correct residual ametropia (myopia, hyperopia, and/or astigmatism), also called bioptics (discussed later in the chapter).

## ADVANTAGES AND DISADVANTAGES OF PHAKIC IOLS

For the advantages and disadvantages of phakic IOLs, see Table 3.7.2.

## INTRAOCULAR LENS POWER CALCULATION

Van der Heijde<sup>21</sup> proposed the theoretical basis for IOL power calculations based on studies of patients implanted with a Worst and Fechner lens, which are directly applicable to other phakic IOLs. The power calculation is independent of the axial length of the eye. Instead it depends on: (1) central corneal curvature (power)–keratometry (K); (2) AC depth; and (3) patient refraction (preoperative spherical equivalent). With current IOL formulas and nomograms great accuracy occurs on IOL power calculations.

TABLE 3.7.2 Advantages and Disadvantages of Phakic IOLs

Advantages	Disadvantages
<ul style="list-style-type: none"> <li>Preserves corneal architecture</li> <li>Potential to treat a large range of myopic, hyperopic, and astigmatic refractive error</li> <li>Allows the crystalline lens to retain its function, preserving accommodation</li> <li>Excellent visual and refractive results (induces less coma and spherical aberration than LASIK)</li> <li>Removable and exchangeable</li> <li>Frequently improve BSCVA in myopic eyes by eliminating minimization effect of glasses</li> <li>Results are predictable and stable</li> <li>Flat learning curve for some models</li> </ul>	<ul style="list-style-type: none"> <li>Potential risks of an intraocular procedure (e.g., endophthalmitis)</li> <li>Nonfoldable models require large incision that may result in significant residual postoperative astigmatism</li> <li>Highly ametropic patients may require additional laser surgery (bioptics) for fine-tuning the refractive outcome</li> <li>May cause irreversible damage (e.g., endothelial cell loss, cataract formation, glaucomatous optic neuropathy)</li> <li>Implantation in hyperopic patients is limited by shallow anterior chambers and can be followed by loss of BSCVA due to loss of magnification effect of glasses</li> <li>Other complications are not rare: pupil ovalization, induced astigmatism, chronic uveitis, pupillary block, pigment dispersion</li> </ul>

BSCVA, Best spectacle-corrected visual acuity; IOLs, intraocular lenses; LASIK, laser-assisted in situ keratomileusis.

## Sizing the Phakic IOLs

The eye's anterior segment anatomy differs significantly among individuals, affecting the indications of phakic IOLs in different refractive errors.<sup>22</sup> Most of the complications of these lenses are related to inappropriate sizing and inaccurate measurements of the AC dimensions.

For the iris-fixated phakic IOLs (i.e., Artisan and Artiflex), sizing is not an issue because these IOLs are fixated to the midperipheral iris, not the angle or sulcus, having the advantage of being one-size-fits-all length (8.5 mm).

For the sulcus-supported phakic IOLs (i.e., implantable collamer lens), different sizes of overall length are manufactured to suit normal variations in intraocular anatomy (e.g., 12.1, 12.6, 13.2, and 13.7 mm). The relationship of the selected overall diameter of the implanted lens to the dimensions of the posterior chamber represents an important determinant of the achieved postoperative vault, which is the term used to describe the measurable distance between the anterior capsule of the crystalline lens and the posterior surface of the ICL (Fig. 3.7.6).<sup>23</sup>

The white-to-white (WTW) diameter (external measurement from limbus to limbus) is the most important factor in determining the ICL size. It provides an approximate estimation of the AC (angle-to-angle [ATA]) and sulcus-to-sulcus (STS) diameters. The WTW is usually measured with the IOLMaster or the Lenstar biometers and checked with manual calipers between the 3 and 9 o'clock meridians. Alternative methods include tomographers such as the Galilei (Ziemer), Pentacam (Oculus), and the Orbscan IIz (Bausch & Lomb). Most studies have used the WTW measurement plus 0.5 mm, rounded to the nearest 0.5 mm increment.<sup>12,24</sup>

The WTW measurement, however, is well known to suffer from significant inaccuracies.<sup>25,26</sup> In a study comparing vertical and horizontal WTW

**Fig. 3.7.6** (A) ICL-V4 in a patient with previous deep anterior lamellar keratoplasty. Observe adequate vaulting (arrow). (B) ICL vault measured with anterior segment OCT. (Courtesy João Marcelo Lyra, MD, Maceió, Brazil.)

measurements with direct anatomical measurements (postfixation) in postmortem eyes, there was no correlation between the horizontal WTW distance and the AC angle diameter; nor was there correlation between either technique of external measurement and the ciliary sulcus diameter.<sup>26</sup>

High-frequency ultrasound biomicroscopy (35 to 60 MHz) has been used to directly measure the STS diameter. It was not until recently, however, that more adequate devices for imaging and measuring the anterior segment became available. The wide-angle high-frequency (50 MHz) ultrasound systems (Eye Cubed, Ellex; VuMAX II, Sonomed; Aviso, Quantel Medical; Artemis, Ultralink LLC; among others) (Fig. 3.7.7) currently are the best tools to measure the STS distance. Although the FDA-approved technique for measurement remains WTW, growing evidence demonstrates that direct sulcus measurement using any of these methods is superior and minimizes the risk of incorrect ICL sizing.

Despite there being no consensus in the literature regarding the upper and lower limits of safe vault, the lens manufacturers suggest that an acceptable amount of vaulting of the lens optic over the crystalline lens is  $1.00 \pm 0.5$  corneal thicknesses (approximately 250–750  $\mu\text{m}$ ). The clinical significance of vault outside of the range of safety resides in the risk of specific adverse events, including pupillary block, anterior subcapsular cataract, pigment dispersion, and glaucoma.<sup>23</sup>

## VISUAL OUTCOMES

Phakic IOLs are the most predictable and stable of the refractive methods for preserving the crystalline lens in high myopia. New improved designs and current methods for sizing and power determination are providing increasing safety and efficacy for the correction of severe ametropias.

In high myopia correction, significant postoperative gain of best-corrected visual acuity (BCVA) over the preoperative levels likely occurs as a result of a reduction in the image—the minimization that is present with spectacle correction of high myopia. A loss of BCVA is uncommon. The loss of contrast sensitivity observed after LASIK for high myopia does not occur after phakic IOL.<sup>27,28</sup> In fact, with phakic IOLs an increase in contrast sensitivity occurs in all spatial frequencies compared with preoperative levels with best spectacle correction.<sup>29</sup> Even for moderate myopia (between  $-6.00$  and  $-9.00\text{D}$ ) phakic IOLs provide better CDVA, contrast sensitivity at high spatial frequencies, and higher percentage of eyes gaining lines of CDVA compared with femtosecond laser-assisted LASIK.<sup>30</sup>

**Fig. 3.7.7** (A) Artemis High-Frequency (50 MHz) 3D-Digital Ultrasound Imaging of the Anterior Segment. Red arrows indicate angle-to-angle distance; yellow arrows indicate sulcus-to-sulcus distance. (B) UBM Vumax II (50 MHz transducer) of a myopic ICL in the posterior chamber. Sulcus-to-sulcus measurement: 12.22 mm. STS diameter measurement is important to determine adequate sizing of the phakic IOL.

## ANTERIOR CHAMBER ANGLE-SUPPORTED PHAKIC INTRAOCULAR LENSES

After the development of foldable AC angle-supported phakic IOLs, the rigid PMMA IOLs were almost abandoned, including the NuVita MA20, ZSAL-4 (Morcher GmbH) and Phakic 6 H2 (Ophthalmic Innovations International). Later, due to safety concerns related to endothelial cell loss, the NewLife and Vivarte (both from IOLTech–Zeiss Meditec) (Fig. 3.7.8) and the Icare (Corneal Inc.) were also withdrawn from the market.<sup>31,32</sup>

A few years ago the AcrySof Cachet (Alcon Laboratories, Inc., Fort Worth, TX) phakic lens was approved by the FDA. The Cachet is a single-piece,

**Fig. 3.7.8** Foldable Hydrophilic Acrylic Angle-Supported Vivarte Lens.

**Fig. 3.7.9 AcrySof Cachet Diagram.** A single-piece, foldable, soft hydrophobic acrylic phakic IOL.

**Fig. 3.7.10 Biomicroscopy Photograph of the AcrySof Cachet Phakic IOL Implant for High Myopic Correction.** (Courtesy Wallace Chamon, MD, São Paulo, Brazil.)

foldable, soft hydrophobic acrylic phakic IOL (Fig. 3.7.9). Four models were available, each with a different overall length. The haptics were designed to allow compression within the angle for IOL stability without creating excessive force that could cause angle tissue damage or pupil ovalization. The vault of the IOL was designed to provide optimal central clearance distance between the IOL and the cornea and the natural crystalline lens (Video 3.7.1) (Figs. 3.7.10 and 3.7.11).<sup>33</sup> The 3-year findings from pooled global studies (United States, Canada, and the European Union) showed favorable refractive results and acceptable safety in patients with moderate to high myopia.<sup>34,35</sup> Recently, however, its distribution was placed on hold due to a significant late-term endothelial cell loss (ECL) in a subset of patients, especially in those with small eyes and patients self-identified to be of Asian race. Data predict that eyes need to be monitored frequently because ~30% of eyes are at risk of early explantation based on the observed ECL rates, and 5% have loss rates higher than 3.9% per year. These rates can accelerate suddenly.

The Kelman Duet (Tēkia, Inc., Irvine, CA) consists of a duet of an independent PMMA tripod haptic and a silicone optic (Fig. 3.7.12). The haptic is implanted first in the AC through a 2.5-mm incision. The optic is then inserted using an injector system. Finally, the optic is fixated in the AC by the optic eyelets and haptic tabs using a Sinsky hook. At 12 months, 17% of eyes had more than 15% ECL.<sup>36</sup> No mid- or long-term data of endothelial cell loss have been reported to date. The Duet is not FDA approved.

**Fig. 3.7.11 Anterior Segment OCT Use in Pre and Postoperative Assessment of a Highly Myopic Eye.** (A) Preoperative measurement of the internal anterior chamber diameter at axis 180 = 11.68 mm. This measurement can be used to determine the total diameter of the phakic implant. (B) Anterior segment OCT in the postoperative assessment of Cachet phakic IOL in a highly myopic eye with angle supported haptics (left and right) and central distance to endothelium: 2.06 mm.

## Complications

### Pupillary Ovalization

Ovalization of the pupil, one of the most prevalent complications of angle-supported phakic IOLs, has a reported incidence of between 7% and 22%.<sup>5,6,9,37-40</sup> Pupillary abnormalities tend to be progressive, being more frequent with longer follow-up visits.<sup>6,9</sup> The most accepted mechanism is related to haptic compression of the angle structure due to an oversized lens causing inflammation of the angle, peripheral synechia formation, and pupillary ovalization. This mechanism was believed to be associated with iris ischemia.<sup>5,41</sup> Iris hypoperfusion was confirmed using indocyanine green angiography (ICGA).<sup>40</sup>

Another associated complication is iris retraction and atrophy<sup>6</sup>; the atrophy usually occurs in the iris sector affected by ovalization. Total sector iris atrophy can occur after progressive pupil ovalization in long-standing cases (Fig. 3.7.13).

### Endothelial Damage

Endothelial damage was the main reason for recalling several AC phakic IOLs from the market.<sup>42</sup>

Two different mechanisms have been proposed to explain the ECL: the excessive proximity of the IOL parts to the corneal endothelium, which may intermittently or permanently be in contact with the posterior cornea<sup>43</sup> or the presence of inflammatory cytokines in the aqueous humor produced by trauma to uveal structures.<sup>44</sup> A follow-up study of more than 15 years of an angle-supported phakic intraocular lens model (ZB5M) for high myopia found a median coefficient of ECL of 17.5% with a rate of 0.97% every year, twice the physiological loss. Careful long-term follow-up of each patient with an AC phakic IOL is necessary to identify patients who may need explants of the IOL.

## Elevation of Intraocular Pressure

Elevation of intraocular pressure (IOP) usually occurs transiently during the early postoperative period but may become chronic due to peripheral synechiae, which affects 2%–18% of patients.<sup>3,5,6,37,38</sup> Another risk is

**Fig. 3.7.12** Foldable “two parts” (silicone optic/PMMA haptics) Kelman Duet lens (A). The haptics are implanted initially through a small incision (B), then the optic is injected (C). The optic-haptics are assembled inside the anterior chamber (D).

**Fig. 3.7.13** Pupil ovalization 2 years after implantation of an angle-supported phakic IOL (A). At 5 years, progressive ovalization was observed and the lens was explanted (B). (Courtesy Emir Amin Ghanem, MD, Joinville, Brazil)

acute glaucoma secondary to pupillary block in the absence of adequate iridectomies.

### ***Uveitis***

Chronic uveitis can be observed after angle-supported IOLs, with rates from 1% to 5%.<sup>3,5,6,37,38</sup> An oversized lens can be a potential cause, compressing the angle structures and altering the blood–aqueous barrier (BAB) permeability. The chronic inflammation may continue for several years, inducing

pupil ovalization, iris atrophy, and other complications, such as glaucoma, cataract, or anterior synechiae.

### ***Cataract***

Cataract after an AC lens—less common than with posterior chamber IOLs—can still occur, mainly due to chronic uveitis and other complications. A meta-analysis of cataract development after AC phakic IOL implantation found an incidence of 1.29%.<sup>45</sup>

**Fig. 3.7.14 Artisan/Verisyse Lens.** Detail of the midperipheral iris stroma enclavated by the haptic claw.

### IRIS-FIXATED PHAKIC INTRAOCULAR LENSES

The Artisan iris-claw (Ophtec)/Verisyse (Abbott Medical Optics, Inc.) lens is fixated to the anterior iris surface by enclavation of a fold of iris tissue into the two diametrically opposed “claws” of the lens (Fig. 3.7.14). The fixation sites are located in the midperiphery of the iris, which is virtually immobile during pupillary movements. The optic vaults approximately 0.87 mm anterior to the iris, providing good clearance from both the anterior lens capsule and the corneal endothelium. The distance from the optic edge to the endothelium ranges from 1.5 to 2.0 mm, depending on the dioptric power, AC anatomy, and optic diameter.

The Artisan/Verisyse has a fixed overall length of 8.5 mm (7.5 mm for pediatric implantations or small eyes), which means a great advantage to the surgeon for not dealing with sizing measurements. Another major advantage of these IOLs is that they can be properly centered over the pupil, even when the pupil is off-center, a relatively common situation among people with high ametropia.<sup>32</sup> Off-center pupils cannot be used as a reference for centration of symmetrical IOLs such as angle-supported and sulcus-fixated IOLs.<sup>32</sup> Additionally, the fixation system inhibits IOL movement,<sup>46</sup> which warrants the correction of astigmatism and may help to correct other vectorial or asymmetrical aberrations in the future.<sup>32</sup> Pupil size in scotopic conditions should be equal or less than body size of IOL + 1.0 mm to reduce the risk of glare and halos (e.g., if the IOL has a body size of 6 mm, the scotopic pupil can be up to 7 mm). A convex, bulging, or volcano shaped iris, usually found in hyperopes, is a contraindication for its implantation. Currently, this lens is mainly used to treat high primary myopia (FDA approved—Models 204 and 206; Fig. 3.7.15),<sup>47</sup> and astigmatism<sup>48–50</sup> in adults. Other indications include:

- Treatment of refractive errors after penetrating keratoplasty.<sup>51–54</sup>
- Treatment of anisometropic amblyopia in children.<sup>55,56</sup>
- Secondary implantation for aphakia correction.<sup>57–59</sup>
- Treatment of refractive errors in patients with keratoconus.<sup>60</sup>
- Correction of progressive high myopia in pseudophakic children<sup>61</sup> and postoperative anisometropia in unilateral cataract patients with bilateral high myopia.<sup>62</sup>

The foldable model (Artiflex/Veriflex, Ophtec) is approved in Europe and is now under clinical investigation for FDA approval. This lens is a convex-concave three-piece phakic IOL with a hydrophobic polysiloxane 6-mm optic and PMMA haptics. The toric model of the Artiflex is also available in Europe.<sup>63</sup>

### Surgical Procedure

Preoperative application of topical pilocarpine for miosis is mandatory to form a protective shield for the natural lens during the insertion and fixation of the iris-claw lens. A constricted pupil facilitates proper centration of the lens. Although a very low risk of pupil-block glaucoma exists (because the vaulted configuration of the Artisan lens ensures a normal aqueous

**Fig. 3.7.15 Artisan/Verisyse Lens.** FDA-approved models (A) 204 (6.0 mm optic) and (B) 206 (5.0 mm optic) for the correction of myopia.

**Fig. 3.7.16 Anterior Segment Optical Coherence Tomography of an Artisan Phakic IOL to Correct High Hyperopia.** The posterior vault is 0.57 mm (distance from the IOL to the lens) and the distance of the anterior surface of the IOL optic to the endothelium (safety distance) at the center is 1.75 mm.

outflow), a peripheral iridectomy during surgery is mandatory. Alternatively, a neodymium:YAG (Nd:YAG) laser can be used preoperatively to create one or two small iridectomies (Videos 3.7.2, 3.7.3, and 3.7.4)

Various incision techniques (e.g., corneal, limbal, or scleral tunnel incision) can be used, usually with peribulbar anesthesia, but topical anesthesia also can be used. Usually a superior limbal or clear-corneal incision is used. Depending on the diameter of the lens used—5.0 mm or 6.0 mm—the incision should be at least 5.2 mm or 6.2 mm, respectively, to avoid difficulties with IOL insertion. The incision is usually located on the steep corneal meridian, minimizing postoperative astigmatism.

The “claw” haptics are fixated to the iris by a process called enclavation, and specially designed bent needles are used. Another option to facilitate

See clip:  
3.7.2  
to  
3.7.4

**Fig. 3.7.17 Toric Artiflex Implantation Technique.** (A) A 3-mm clear corneal incision is created. (B) Two paracentesis are created parallel to the limbus, oriented toward the enclavation site. (C) Lens is removed from package and held with special forceps. (D) The Artiflex is mounted in the implantation spatula. (E) The optic edge bends downward during the lens insertion. (F) and (G) Lens is rotated, centered on the pupil and positioned according to the preoperative markings on the cornea (toric model). The superior claw is grasped and the enclavation is performed with the VacuFix. (H) Cohesive viscoelastic material is removed and peripheral iridectomy is performed. Main incision is closed.

controlled and reproducible enclavation in the exact desired spot is the VacuFix (Ophtec) (Fig. 3.7.17). This is especially important for the toric models, to facilitate cyclotorsion control.

Two 1.0-mm side-port incisions at 10 and 2 o'clock positions are required for enclavation. The lens is implanted vertically through the incision, then

rotated and centered in front of the pupil with the haptics at 3 and 9 o'clock positions. When using toric models, the correct axis of implantation will be calculated preoperatively. Limbal marks at the slit-lamp or iris marks with Nd:YAG should be done in the axis of implantation helping to control cyclotorsion and increasing axis enclavation precision.

**Fig. 3.7.18** Blunt Iris Entrapment Needles Can Be Used to Create a Fold of Midperipheral Iris Tissue Through Vertical Movement of the Needle.

**Fig. 3.7.19** Inadequate Iris Enclavation (arrow) increases the risk of focal iris atrophy, uveitis, and dislocation of the IOL.

The AC is filled with cohesive viscoelastic material, usually high-viscosity sodium hyaluronate injected through one of the puncture incisions to create a deep AC to maintain working space in the AC. If additional viscoelastic material needs to be injected during surgery, care should be taken not to let it slip under the IOL. It should be used as a stabilizing agent that presses the implant onto the iris surface.

Centration and fixation of the IOL are probably the most critical steps of the procedure, and their accuracy influences the postoperative results. The pupil is used as a reference for centration. Fixation is performed by gently creating an iris fold under the claw and then entrapping the iris fold into the claw (Fig. 3.7.18). If adjustment of the lens is needed after fixation, the iris must first be released before the lens is moved. At the end of surgery, it is not unusual to have mild ovalization of the pupil due to the effect of the miotic agent.

The number of stitches depends on the type of incision. Watertight wound closure is of paramount importance to prevent a shallow AC from leading to IOL–endothelial contact in the immediate postoperative period. A small incision will help minimize surgically induced astigmatism and inflammation.

When the foldable Artiflex is used, a small 3.2-mm clear cornea incision may be preferred. A special Artiflex implantation spatula and a lens holder are necessary. The lens should be held by the haptics as the optic is made of polysiloxane and should not be touched during surgery.

The viscoelastic material should be completely removed, preferably with automated irrigation/aspiration system as it may induce an early postoperative IOP rise.

Topical corticosteroids and antibiotics are usually prescribed for 2–4 weeks after surgery. Regular follow-ups are recommended, in particular long-term evaluations of the corneal endothelium. Correct timing of suture removal is critical in reducing residual astigmatism.

## Complications

### Glare and Halos

The incidence of glare and halos is greater with the 5.0-mm than with the 6.0-mm optic diameter.<sup>64,65</sup> The general incidence has varied from 0 to 8.8%. In the FDA prospective study, as many as 13.5%–18.2% of the patients had glare and halos postoperatively, but approximately 10%–13% had these symptoms preoperatively with an improvement after surgery. Pupils larger than 5.5 mm are at a significantly increased risk for glare and halos.<sup>66</sup>

### Anterior Chamber Inflammation/Pigment Dispersion

Cases of severe iritis are rarely observed after surgery but can occur after repeated traumatic attempts at iris enclavation or occasionally without any predisposing factors.<sup>67,68</sup> Pigment dispersion syndrome has occasionally been observed. A known mechanism is poor fixation/enclavation of the IOL to the iris with subsequent pseudophakodonesis (IOL movement), which may cause chronic inflammation with the need for reintervention for refixation (Fig. 3.7.19). Poor fixation has been observed in as many as

**Fig. 3.7.20** Nonpigmented (cellular) Deposits on the Posterior Surface an Artiflex Lens.

3% of cases.<sup>65</sup> In the FDA trial, iritis was observed in 0.5% of cases and poor fixation in 2.1%.

With the Artiflex, Tehrani et al.<sup>69</sup> observed an increased incidence of pigment dispersion (12.2%), believed to be due to a slight step within the implant in the area of the connection of the foldable silicone optic to the rigid haptic (claw), which may have caused iris pigment abrasion during pupillary movement. Another complication in about 12% of patients is a nonpigment deposition on the polysiloxane optic of the Artiflex lens. Treatment, which is successful in almost all cases, is with topical corticosteroids.<sup>70a</sup> The deposits tend to diminish after the third month and usually disappear after 12 months, even when not treated with corticosteroids. In one of our cases, surface IOL cleaning was needed once topical treatment was not successful (Fig. 3.7.20).<sup>70b</sup> A re-enclavation or even an explantation can be considered if the deposits recur.

### Endothelial Cell Loss

Intraoperative trauma is considered the main cause of early cell loss. Investigators have found an acceptable mean endothelial loss of 2.8%–9.2% 2 years following iris-claw phakic lens implantation,<sup>47,65,69,71,72</sup> which is similar to results of posterior chamber IOL implantation.<sup>73</sup> Menezo et al.<sup>65</sup> noted endothelial cell loss of 13.4% at 4 years, without morphometric changes. The largest cell loss was observed in the first 6 months after surgery.

In the FDA trial, a mean corneal endothelial cell change of 4.8% was observed 3 years after surgery.<sup>66</sup> Artisan phakic IOLs implanted in eyes with AC depths less than 3.2 mm exhibited the greatest cumulative endothelial

cell loss (9%) at 3 years. The FDA panel then contraindicated the use of this lens for patients with an AC depth of less than 3.2 mm. Morral et al.<sup>74</sup> observed that Artisan/Artiflex implantation did not produce significant ECL up to 10 years after surgery compared with corneal refractive surgery and unoperated eyes. Patients should never rub their eyes and never press them against the pillow at night.

### Glaucoma

Postoperative glaucoma after Artisan lens implantation can occur due to residual ophthalmic viscosurgical device in the AC, dispersion of iris pigment during surgery with partial occlusion of the trabecular meshwork, use of topical corticosteroids, and postoperative inflammation.<sup>65,68,72</sup> Temporary ocular hypertension was demonstrated in a prospective study of 100 eyes with Artisan IOL. IOP showed a mean increase of 2.1 mm Hg at 3 months after surgery but a return to preoperative levels by 6 months.<sup>75</sup> In the same study, one lens was explanted due to chronic high IOP at 11 months. In the FDA study, no case of raised IOP requiring treatment was observed.

### Iris Atrophy or Dislocation

Despite successful implantation of an Artisan lens, there is a risk of subsequent IOL dislocation. In the FDA trial, IOL dislocation occurred in five cases (0.8%) at 3 years. IOL dislocation can occur due to iris atrophy at the site of enclavation, usually when a small amount of tissue is entrapped, or due to blunt ocular trauma, as reported previously in two cases<sup>76,77</sup> (Fig. 3.721). Repositioning of the lens may be done with an excellent visual outcome in most cases.

### Cataract

Nuclear cataract (NC) developed in 7 of 231 eyes (3%) with an Artisan lens after 8 years follow-up in one study.<sup>78</sup> Patients older than 40 years of age at implantation of the IOL and axial length greater than 30 mm were factors significantly related to NC formation.<sup>78</sup> A meta-analysis of cataract after iris-fixated phakic IOL implantation found an incidence of 1.11%.<sup>45</sup> In the FDA trial, the cumulative incidence of lens opacity was 4.5% (49/1088 eyes). The majority of these opacities were not visually significant. During the study, four opacities were determined to be visually significant and three required cataract extraction. The authors pointed out that the rate of cataract surgery in the general population over 40 years of age is 1.7%–10.8%.<sup>66</sup>

### Other Complications

Other complications include hyphema,<sup>71</sup> intermittent myopic shift (of 4.00 D),<sup>79</sup> retinal detachment, and giant retinal tears.<sup>71,80,81</sup>

## POSTERIOR CHAMBER PHAKIC INTRAOCULAR LENSES

Since 1986, when Fyodorov first implanted a phakic IOL in the prelenticular space to correct high myopia, several posterior chamber phakic IOLs of his derivation have been developed.<sup>12,82</sup> Results with phakic IOL materials and designs used to date suggest that both biocompatibility with and adequate spacing from sensitive intraocular structures are required for improved safety in all patients. For implantation of a phakic IOL in the prelenticular space, we would ideally desire materials that would allow permeability of nutrients and circulation of aqueous humor and would not cause crystalline lens or zonular trauma.

Until recently, two models of posterior chamber phakic IOLs were available on the market, the phakic refractive lens and the implantable collamer lens. Despite initial promising results with the PRL, it was withdrawn from the market due to safety concerns.

The PRL (IOLTech/CIBA Vision) (see Fig. 3.73), a model based on previous work by Fyodorov et al.,<sup>12,13,24</sup> was a silicone single-piece plate design IOL that had a concave posterior base curve mimicking the anterior curvature of the crystalline lens. Earlier designs of this IOL caused cataract because of mechanical touch, impermeability of nutrients, and stagnation of aqueous flow without the elimination of waste products.<sup>13,14,83</sup> Further improvements in the vaulting reduced the incidence of cataract, but UBM studies documented that the PRL was located on the zonules in most cases.<sup>84</sup> After reports of PRL decentration and dislocation into the vitreous cavity the lens was withdrawn from the market.<sup>85–87</sup>

ICL: In 1993, a posterior chamber phakic IOL made of Collamer (0.2% collagen and 60% hydroxyethyl methacrylate copolymer) was developed.<sup>88–90</sup> The ICL (STAAR Surgical Co.); Fig. 3.722 is designed to be implanted in the posterior chamber supported in the ciliary sulcus.

**Fig. 3.721** (A) Artisan Dislocation After Blunt Trauma. Note the avulsion of iris stromal tissue in the site of enclavation. (B) and (C) Anterior segment OCT of a dislocated Artisan intraocular lens. IOL optic touch to endothelium (left in both figures) and correspondent thickening of the cornea (edema).

Collamer is a hydrophilic flexible material with a high biocompatibility and permeability to gas (oxygen) and metabolites.<sup>88</sup> These features and the free space left between the IOL and the crystalline lens, named “vault,” should allow the crystalline to have a normal metabolism and thus avoid the development of cataracts. Yet cataract formation, pigment dispersion, and glaucoma still are the main complications.<sup>91–93</sup> The FDA-approved model of the ICL—the Visian ICL V4 (Fig. 3.722A), a rectangular single-piece IOL, 7 mm wide, with greater vaulting than the V2 and V3 models—has been associated with a decrease in the frequency of lens opacification.<sup>94,95</sup> A newer design, currently available outside the United States, the V4c Visian ICL with Aquaport (Fig. 3.722B), incorporates a 0.36-mm diameter port in the center of the optic. The presence of this port obviates the need for preoperative iridotomies.

### Surgical Technique

A combination of topical mydriatics (e.g., cyclopentolate 0.75% and phenylephrine 2.5%) is applied three times 30 minutes before surgery to obtain good pupil dilation. For toric cases the 0° and 180° horizontal corneal axis are marked while the patient is sitting upright to control cyclotorsion while

**Fig. 3.7.22** (A) ICL V4 and (B) V4c toric with central Aquaport. (C–E) Myopic ICL. (C) Biomicroscopic slit demonstrating the distance ICL to the crystalline lens. (D) UBM (50 MHz) quantitatively assessing lens vault (distance ICL to lens) = 590 microns; and (E) UBM showing the proximity of the ICL haptic to the ciliary processes and zonulae.

**Fig. 3.7.23** A Posterior Chamber Lens (ICL) Is Inserted Through a Small Incision With an Injector. (Courtesy Glauco R. Mello, MD, Curitiba, Brazil.)

**Fig. 3.7.24** After the Lens Unfolds, the Footplates Are Placed Underneath the Iris.

lying supine. Topical or peribulbar anesthesia are usually preferred. A 2.7- or 3.0-mm temporal clear corneal tunnel, and two paracentesis are created. Following the placement of cohesive viscoelastic, the posterior chamber IOL is introduced into the AC using an injector (**Fig. 3.7.23**) (Video 3.7.5).

While the IOL unfolds, its proper orientation must be checked. Each footplate then is placed one after the other beneath the iris with use of a specially designed, flat, nonpolished manipulator, without placing pressure on the crystalline lens (**Fig. 3.7.24**). The surgeon should avoid contact with the central 6.0 mm of the lens, as any contact might damage the thin lens optic. Except for the newest model (V4c), a small peripheral iridectomy should be performed to prevent pupillary block. Then the viscoelastic material is removed with irrigation–aspiration, and acetylcholine (Miochol) is injected. Corticosteroid–antibiotic eyedrops are prescribed for 4 weeks.

## Complications

### Cataract

Cataract is the most crucial concern for the future of posterior chamber phakic IOLs (**Fig. 3.7.25**). Cataract may form as a result of trauma to the crystalline lens during the implantation procedure or due to long-term contact between the IOL and the crystalline lens. Metabolic disturbances

induced by the implant also may be partially responsible for cataract formation.

A meta-analysis of cataract development after different posterior chamber phakic IOLs found that 223 of 1210 eyes developed new-onset cataract.<sup>45</sup> Of these, 195 were anterior subcapsular. The overall incidence of cataract formation was 9.6%. In the ICLV4 FDA trial with a mean follow-up of 4.7 years, a cumulative probability estimate of 6%–7% of anterior subcapsular opacities was found more than 7 years after implantation of the Visian ICL.<sup>96</sup>

In a more recent meta-analysis comprising 2592 eyes, the occurrence of cataract formation with the V4 ICL models was 5.2%. Of those, 43.4% were reported within 1 year, 15.4% between 1 and 3 years, and 35.3%  $\geq 3$  years after ICL implantation.<sup>97</sup> In a retrospective review of 133 consecutive eyes implanted with the V4 ICL model, the observed rate of phacoemulsification increased from 4.9% at 5 years to 18.3% at 10 years after ICL implantation, and 13% of eyes developed ocular hypertension that required topical therapy at 10 years. A smaller vault height was associated with the development of lens opacity.<sup>98</sup> Another study with 84 eyes with V4 ICL reported a rate of phacoemulsification of 17% at 10 years.<sup>99</sup>

The treatment of cataract in patients implanted with posterior chamber phakic IOLs is not difficult. Explantation of the ICL is easily performed

**Fig. 3.7.25** Anterior Cortical Cataract 1 Year After ICL-V4 Implantation in a Patient With Previous Intracorneal Ring Segment for Keratoconus. (Courtesy João Marcelo Lyra, MD, Maceio, Brazil).

through the same incision. Phacoemulsification and posterior chamber IOL implantation can be done in a routine fashion.<sup>100</sup>

### ICL Replacement

ICL exchange for insufficient or excessive vault is an uncommon complication. In a cohort of 616 eyes implanted with V4 ICLs sized according to WTW and ACD measurements, 16 eyes (2.6%) had lens replacement.<sup>101</sup> Eight surgeries (50%) were performed because of low vaulting ( $\leq 100 \mu\text{m}$ ) and another 8 (50%) because of too high vaulting ( $\geq 1000 \mu\text{m}$ ). In the US FDA trial using the same sizing methodology, ICL replacement for insufficient or excessive vault was reported in five of 526 eyes (1.0%).<sup>102</sup> In the absence of complications, however, ICL replacement remains a matter of medical judgment. On the other hand, excessive vault in the presence of compromised AC angle function (Fig. 3.7.26) (Video 3.7.6) and insufficient vault in the presence of visually significant cataract are indications for surgical intervention.<sup>23</sup>

See clip:  
3.7.6

### Pigmentary Dispersion and Elevated Intraocular Pressure

Pigmentary dispersion syndrome occurs when the iris is abraded and releases pigments into the aqueous humor. Because of the close position to the iris and ciliary sulcus, the placement of posterior chamber phakic IOLs may increase the risk of pigmentary dispersion<sup>14,24,92</sup> (Fig. 3.7.27). Pigmentary reaction has been described with rates between 0% and 15.5% with posterior chamber phakic IOLs and is frequently associated with elevated IOP. Sanders et al.<sup>102</sup> reported two eyes out of 526 (0.4%) with increased IOP requiring treatment at 3 years postoperative. Guber et al.<sup>98</sup> reported that at 10 years, 12 eyes (12.9%) had developed ocular hypertension that required topical medication, which raises some concern about the long term.

### Endothelial Cell Damage

Although endothelial cell loss is a major concern with AC IOLs, it is not such an important problem with posterior chamber phakic IOLs. In the ICL FDA trial, cumulative cell loss over the first three postoperative years was 8.4%–9.7%, depending on the method of analysis.<sup>94</sup> Most loss occurred in the first year and is considered to be due to surgical trauma.

### BIOPTICS

Zaldivar et al.<sup>104</sup> introduced the term “bioptics” in the late 1990s to describe the combination of phakic IOL implantation followed by LASIK in patients with extreme myopia, high levels of astigmatism, and in patients whose lens power availability was a problem. The concept of first implanting a phakic IOL to reduce the amount of myopia and then fine-tuning the residual correction with LASIK has gained appeal.

When an AC phakic IOL combined with LASIK is planned, the corneal flap can be created just before the insertion of the lens. Then, usually after 1 month, the flap is lifted for laser correction of the residual ametropia.

**Fig. 3.7.26** (A) Anterior chamber angle closure and excessive vault after ICL V4 implantation in a patient with high myopic astigmatism after previous deep anterior lamellar keratoplasty. (B) The ICL was replaced for a smaller size through a microincision (arrow). (C) After replacement, a normal vaulting was observed. (Courtesy Walton Nosé, MD, PhD, São Paulo, Brazil.)

This two-step technique was called adjustable refractive surgery (ARS) by Guell.<sup>105</sup> The rationale for performing the flap first is to avoid any possibility of contact between the endothelium and the IOL during the suction and cut for the LASIK procedure. Most authors believe that the corneal flap can be created despite the presence of an AC phakic IOL. The combination of phakic IOLs and LASIK is a safe, effective, predictable, and stable procedure for the correction of high myopia and hyperopia.

### CONCLUSION

The field of phakic IOLs has greatly progressed in recent years. The increased knowledge on anterior segment anatomy and the availability of better imaging technologies along with improved IOL designs and materials and surgical techniques have led to higher success rates with these lenses. Compared with corneal refractive surgery, phakic IOLs compete favorably for the correction of high ametropias with increasing predictability, efficacy, safety, and quality of vision.

# Astigmatic Keratotomy: The Transition from Diamond Blades to Femtosecond Lasers

3.8

Kerry K. Assil, Joelle A. Hallak, Pushpanjali Giri, Dimitri T. Azar

## Definitions:

- Astigmatic keratotomy (AK) is an incisional procedure in which a diamond blade or a femtosecond laser is used for the correction of astigmatism.
- Radial keratotomy (RK) is a procedure in which radial incisions are used to correct myopic spherical refractive error. The lower predictability and higher complication rates of RK relative to laser refractive surgery have reduced its utility for the correction of myopia.

## Key Features

- The effect of incisional keratotomy is influenced by corneal wound healing and patient age.
- For astigmatic keratotomy, the surgeon must screen surgical candidates for myopic or planospherical equivalents.
- The axis of astigmatism is important for the placement of AK incisions. Sound clinical judgment is needed when disparity occurs between corneal topography and clinical refraction.
- Complications of incisional keratotomy may be reduced by adequate marking of the visual axis, adequate corneal incision shape and depth, and avoidance of corneal perforations.
- Postoperative complications include progressive hyperopia, progressive wound gaping, induced astigmatism, and contact lens intolerance.
- Femtosecond laser arcuate keratotomy (femtosecond AK) is an effective alternative to AK. Laser arcuate resection (LAR) is an effective alternative to manual wedge resection for high postkeratoplasty astigmatism.

## HISTORICAL REVIEW

### Incisional Keratotomy

The diamond knife, although still in use today, is being replaced in many centers by the femtosecond laser with its ultrashort pulses capable of chiseling precise incisions on the cornea. Femtosecond lasers have garnered acclaim in terms of generating corneal incisions with greater precision, accuracy, safety, predictability, and reproducibility.

Incisional keratotomy now is mainly limited to astigmatic keratotomy at the time of cataract surgery and, rarely, to two-incision radial keratotomy (RK) for patients with low-grade myopic astigmatism who are not good candidates for laser in situ keratomileusis (LASIK) and photorefractive keratectomy (PRK).

Several options are available today for femtosecond laser AK: femtosecond laser astigmatic keratotomy (femtosecond AK) and intrastromal astigmatic keratotomy (ISAK). Methods for astigmatism correction can be performed alone or in combination with other procedures such as cataract surgery. Further, the correction can be done for natural or surgery-induced astigmatism such as postkeratoplasty astigmatism.

## SURGICAL TECHNIQUES FOR ASTIGMATIC AND RADIAL KERATOTOMY

The surgical techniques for AK and RK<sup>1-4</sup> (rarely used today) have many common aspects. AK remains a surgical option for correcting high astigmatism (e.g., postkeratoplasty astigmatism) that is beyond excimer laser correction or for the correction of smaller degrees of astigmatism in patients undergoing cataract surgery. Femtosecond AK has increased the predictability and improved the safety of AK.<sup>5,6,7</sup> Although limbal relaxing incisions have become popular as well, they do not have the tensile strength of Descemet's membrane, which fortifies a corneal incision.

## Preoperative Considerations

### Patient Selection

In selecting patients for AK, the surgeon must screen surgical candidates for myopic or planospherical equivalents. AK does not, as a general rule, benefit patients who have hyperopic astigmatism in which the spherical equivalents are relatively unaffected or associated with a further hyperopic shift.

Ideal candidates for AK, in addition to having a myopic or planospherical equivalent, have no keratoconus, are intolerant of contact lenses, and experience meridional magnification and distorted peripheral vision with high-cylinder spectacles.

### Visual Axis Determination and Marking

The use of scanning slit topography or Scheimpflug-based topography along with clinical refraction will help confirm the positioning of the planned AK incisions. Modern topographers provide an estimate of pachymetry at the location of the intended AK incision sites.<sup>8,9</sup>

A corneal light reflex used to guide procedure centration serves only to approximate the physiological visual axis location, because a coaxially aligned light reflex corresponds to the center of the corneal optical system and not the true visual axis. Studies have demonstrated this site to be associated most closely with the physiological visual axis.<sup>10</sup>

For marking of the visual axis, the administration of a drop of fluid over the corneal apex may enhance an otherwise dull corneal light reflex. A Sinskey hook is used to indent gently the epithelium that overlies the visual axis. If the epithelial indentation is not visualized readily, a Weck cell may be applied to the central epithelium, which enhances the central epithelial mark.

Treatment alignment is important for successful correction of astigmatism. The results of vector analysis have indicated that treatment decentration by 5°, 15°, and 30° corresponds to losses of the flattening effect by 1.5%, 13.4%, and 50%, respectively. Moreover, complete loss of the flattening effect is seen with treatment misalignment of 45°.<sup>11</sup>

### Intraoperative Corneal Pachymetry

The paracentral corneal thickness (1.5 mm from the visual center, at the 3-mm central clear zone) is measured at both the temporal site and the thinnest paracentral site, as previously established by pachymetry at the screening examination. Most often, this thinnest paracentral site coincides with the paracentral temporal (or inferotemporal) site as the region closest to the anatomical corneal center. If the two sites do not coincide,

the diamond blade is set to 100% of the thinner of the two intraoperatively measured sites using a calibration microscope.

## Incision Technique

Astigmatic incisions, either arcuate or tangential, produce maximal flattening in the meridian of the incision when they are placed within 2.5–3.5 mm of the visual axis, which also is within the 5–7 mm optical zone. Incisions made closer than the 5-mm optical zone cause visual disturbances. Incisions beyond 7 mm (such as limbal relaxing incisions [LRIs]) have a diminished effect on central corneal flattening.

When arcuate incisions are lengthened, increasingly greater degrees of astigmatic correction are provided, up to an arc length of 90°. Beyond an arc length of 90°, no reliable additional flattening occurs. Stacking multiple rows of astigmatic incisions is neither productive nor advised. Incisions carried out at progressively smaller optical zones may result in global corneal flattening. Such incisions may be associated with increased incidence of irregular astigmatism.

### Diamond Blade–Assisted AK

The diamond blade–assisted AK procedure is a manual process that requires marking the optical zone of the desired incision, marking the steep axis of astigmatism according to the appropriate arc length, and then determining the corneal thickness at the optical zone with ultrasound pachymetry before inserting the blade into the cornea to make the incision. A sterilized diamond knife blade then is mounted onto the sterile mounting block of the calibration microscope with the knife footplates set to zero and the diamond either extended to 550 mm or set at the thinnest paracentral screening pachymetric reading. Once real-time, intraoperative ultrasonic pachymetry is obtained, the diamond-tip extension is adjusted to the newly selected level. In this way, a minor adjustment is generally all that is needed, and it can be carried out in only a few seconds. When LRIs are being applied during cataract surgery, a preset blade is often used without the need for precalibration.<sup>12,13</sup>

Although this AK procedure has the potential to reduce high degrees of astigmatism, the postoperative outcomes are often accompanied by complications such as wound gape, perforation, skin lesions, epithelial inclusion, higher order aberrations, and poor predictability. LRIs have become popular as well, but the tensile strength of Descemet's membrane that strengthens a corneal incision is absent in laser arcuate resection (LAR).

### Full Penetrating Femtosecond AK

Femtosecond AK corneal surgery creates arcuate incisions to flatten the cornea. AK incisions are generally placed in the steep corneal meridian and result in flattening of the steep meridian (often associated with a compensatory steepening “coupling” effect of the orthogonal flat meridian). A coupling ratio is defined as the ratio of the values of the flattening of the steep meridian and the steepening of the orthogonal flat meridian after placement of AK incisions.<sup>14</sup> A coupling ratio equal to 1 indicates an unchanged spherical equivalent (SE) after the procedure due to equal flattening and steepening of the two meridians. A coupling ratio less than 1 indicates a SE shift toward myopia, and conversely, a coupling ratio greater than 1 indicates a SE shift toward hyperopia. Corneal topography or tomography, along with refraction, are performed in planning the femtosecond AK incisions.<sup>15</sup> Nomograms are then used to determine the arc length and the optical zone to achieve the desired astigmatism correction.

Although prior nomograms existed, developing their own nomogram based on a series of cases was important for each surgeon as demonstrated by the different surgery results of the femtosecond procedure experienced by some surgeons compared with the manual AK technique. Donnenfeld and Nichamin LRI nomograms were most commonly used as the baseline for the laser nomograms. Some surgeons altered both the blade nomogram and the laser's power output to come up with an effective approach for using the IntraLase laser. The modified Lindstrom nomogram is the most widely implemented nomogram for planning femtosecond AK incisions. Usually, when using the modified Lindstrom nomogram, surgeons recommend adding 0.05 diopters (D) to the planned astigmatism correction per year for patients less than 30 years old and subtracting 0.02 D per year for patients over 30 years old. Additional nomograms have been developed for femtosecond AK as well.

When femtosecond laser incisions are made, a series of spherical spots are created adjacent to each other tightly so that the final effect is similar to a wide-open incision made using the traditional diamond blade. Alternatively, this process can be adjusted by altering the laser energy and the spot size. Lowering the laser energy creates a weaker shot, making the

spot sizes smaller. This way the spots never really connect, which reduces the effectiveness of the femtosecond laser–created AK incision compared with those created using the diamond blade. However, the incision is made tighter, ensuring that it does not open immediately. The laser pulses are typically placed around 3  $\mu$ m on both the spot and layer separations.

### Femtosecond Intrastromal Astigmatic Keratotomy (ISAK)

Intrastromal incision is conceptually different from a manual LRI or full penetration astigmatic incision in that there is no breakage of Bowman's layer during the procedure. Compared with penetrating AK incisions, the optical zone is made a little smaller and the arc angle is made a little longer in ISAK.<sup>16</sup> The complete intrastromal nature of the incision allows the healing of the realigned stroma without wound gaping or epithelial plug formation. To ensure proper alignment, limbal marks can be made with a sterile pen placed at the 3 o'clock and 9 o'clock positions at the slit lamp just before the procedure. The incision details such as the depth, optical zone, and arc length can be preprogrammed into the femtosecond laser post limbal marking, after which the procedure can be carried out in a very similar manner to LASIK flap creation with the femtosecond laser. Patients with mixed astigmatism with a plano spherical equivalent will best benefit from the ISAK procedure, because the AK incisions are neutral in relation to myopia or hyperopia.<sup>17</sup> Thus, ISAK is a great additional potential option available for femtosecond laser users, especially for astigmatism ranging from 0.50 to 2.75 D of cylinder.

The variables in performing ISAK incisions are arc length on the nomograms and the surgical platform. As for femtosecond AK, Donnenfeld, Nichamin LRI, and modified Lindstrom nomograms are used as starting points for performing ISAK. However, additional nomograms have been determined for ISAK incisions combined with other procedures such as phacoemulsification.<sup>18</sup> The surgeons suggest an incision depth of 80% or 90%.

ISAK confers a unique advantage to the process of astigmatism correction by virtue of its intrastromal nature. The intrastromal incisions can be titrated easily by opening of the incision, and they can be performed easily in a minor procedure room or right at the slit lamp.<sup>17</sup> It is easiest to open the incision if the anterior edge of the incision is left just under the Bowman's layer.

### Wedge Resection Using Laser Arcuate Resection (LAR)

LAR is a standardized technique in which intersecting arcuate cuts are used to perform a wedge resection for the correction of high astigmatism through corneal steepening. The arcuate wedges to be excised are placed in the flat meridian. A simple formula is used to estimate the relative size and location of the arcuate cuts based on the radii of curvature and desired wedge width to be resected. The feasibility of the procedure was established in porcine corneas before treatment of a patient with 20.00 D of postkeratoplasty astigmatism.<sup>13</sup> The astigmatism was reversed (Fig. 3.8.1), and suture removal resulted in a 14.5 D reduction of astigmatism. LAR can be an effective alternative to manual wedge resection, allowing easier, more controlled, and more precise excision of tissue in width, length, and depth.<sup>13</sup>

## Surgical Protocol

When AK is planned, careful attention to quantitative keratography (corneal topography) may be valuable, because paired incisions based on either the standard keratometer measurements or the refraction alone may be inaccurate. If a manifest refraction fails to yield the patient's potential acuity, irregular astigmatism may be present, and a topographical analysis is useful.

The visual axis is determined first, followed by selection of the appropriate optical zone, incision number, and length, as directed by the nomogram.

### Axis of Astigmatism

When disparity occurs between corneal topography and clinical refraction, the surgeon needs sound clinical judgment on a case-by-case basis. In such circumstances, if topographical analysis demonstrates orthogonal astigmatism, the surgeon may proceed according to the manifest refraction, as this provides the physiological combined (lenticular plus corneal) astigmatism. Alternatively, in cases of nonorthogonal astigmatism (when the two steep hemimeridians differ by any angle other than 180°), if the spherocylindrical reconstruction of the topographical pattern is consistent with the refraction, the incisions are placed as indicated by the topographical map.

**Fig. 3.8.1** (A) Preoperative corneal topography of the right eye demonstrated 20.0 D of post-PKP astigmatism. (B) Intraoperative view during wedge tissue removal (0.5 mm width) after LAR. The tissue was easily peeled off the wound. (C) Single 10–0 nylon sutures were placed. (D) Biomicroscopy appearance 1 month following LAR. (E) At 4 months, the corneal topography showed a decrease in topographical astigmatism to 6.3 D. (Reproduced with permission from Ghanem RC, Azar DT. Femtosecond-laser arcuate wedge-shaped resection to correct high residual astigmatism after penetrating keratoplasty. *J Cataract Refract Surg* 2006;32:1415–19.)

Once the desired axis of astigmatic correction has been determined, this needs to be translated onto the cornea. Because the astigmatic axis is defined so carefully with the patient in an upright position without sedation or a lid speculum, one must not estimate the surgical axis intraoperatively with the patient in a supine position or sedated or with a lid speculum in place. Cyclotorsional rotation of the globe may occur and introduce significant error.

For control, with the patient seated at the slit lamp, epithelial marks are placed on either the vertical or horizontal axis. Using the slit beam for centration and with the contralateral eye covered, the patient fixates straight ahead first on the slit-lamp light source. Fixation on the slit-lamp filament

at eye level and from head-on provides a virtual image of the light filament, which falls at the center of the corneal optical system and closely approximates the visual axis. The epithelium is abraded at the outer margins along the long axis of the beam using a Sinskey hook.

After true 90° or 180° is marked precisely at the slit lamp, the true visual axis is determined in the operating room under the operating microscope. With the 90° (or 180°) position determined precisely (reference axis), any desired axis may be marked using an axis marker and a surgical marking pen.

After appropriate marking of the astigmatic axis, pachymetry is carried out at the selected optical zone over the incision sites. The diamond blade

is set at 100% of the measurement at the thinner of the two sites. With the globe fixated, the corneal marks are incised.

The use of guarded diamond knife blades is advisable. The conjunctiva is grasped close to the limbus, where it fuses with Tenon's capsule and enables stable fixation; this region also is anesthetized more deeply than are the posterior conjunctiva and sclera.

The surgeon needs patience when secondary enhancements to AK are planned and performed. AK incisions require more time to stabilize than do radial incisions, so enhancement should be deferred for a minimum of 6 weeks after the primary procedure. A computerized videokeratography system is indispensable when the enhancement of an AK procedure is carried out. Caution is advised in treating overcorrected AK patients. If the resultant refractive error is one of hyperopic astigmatism, the original incisions may be reopened, the fibrous plug removed, and the wound margins approximated using a 10–0 nylon suture. Likewise, if an astigmatic incision is placed incorrectly in the flat axis, the wound margins are approximated using 10–0 nylon suture. Alternatively, if the residual refractive error is myopic astigmatism, further astigmatic incisions may be placed in the newly defined, steep hemimeridian. Such incisions are shorter than otherwise indicated, because the cornea has now demonstrated an excessive response to the initial incisions and could respond in like fashion to any further astigmatic incisions.

## Postoperative Protocol

At the termination of the procedure, diclofenac sodium, mild corticosteroid, and anti-infective agent drops (such as tobramycin, ciprofloxacin, ofloxacin, or norfloxacin) can be given. The diclofenac drops are discontinued on postoperative day 2 to avoid masking early keratitis and to minimize the risk of a toxic response.

## OUTCOME COMPARISON FOR VARIOUS ASTIGMATISM CORRECTION METHODS

In 2008, Harissi-Dagher and Azar<sup>5</sup> first reported the outcomes of high astigmatism correction in postkeratoplasty patients treated with femtosecond laser–assisted paired arcuate keratotomies. The report included two patients whose outcome measures included best-corrected visual acuity (BCVA), refraction, keratometry, and topography findings. The patients' BCVA improved from 20/100 and 20/200 to 20/30 and 20/60, respectively, without any postprocedure complications such as microperforations, graft rejection, or graft failure.

Newer versions of femtosecond laser platforms utilize both static and real-time optical coherence tomography (OCT) imaging systems to provide better accuracy and precision for the determination of planned AK incisions. LenSx is an example of a new generation femtosecond laser platform that has a video microscope and OCT integrated to facilitate visualization of detailed corneal structures in real time. Significant successes in the reduction of high residual astigmatism have been reported with this AK technique because of the production of precise and reproducible incisional cuts with proper depth, length, and curvature. Some examples of such success include astigmatism reduction rates of 36% by Kumar et al.,<sup>19</sup> 47% by Buzzonetti et al.,<sup>20</sup> 54% by Cleary et al.,<sup>21</sup> 55% by Hoffart et al.,<sup>6</sup> and 65.5% and 89.42% by Viswanathan et al.<sup>15</sup>

The efficacy of the astigmatic incisions has been shown to be dependent on the depth and length of the incisions, the optical zone, and the age and gender of the patient. These reports have been made based on studies on both live patients and on cadaver eyes. Incisions can be arcuate or beveled, full penetrating or intrastromal. Clearly et al.<sup>21</sup> performed paired femtosecond AK incisions at a bevel angle of 135° at a depth of 65%–75%, and with arc length of 60°–90°. The outcomes of these beveled incisions were compared with a case of perpendicular femtosecond AK incision. They reported an astigmatism reduction rate of 54%, which is comparable or better than those achieved with vertical incisions at similar depths. The major advantage observed from the beveled incision technique compared with the regular perpendicular incision technique was the lack of wound gaping.

## COMPLICATIONS AND MANAGEMENT OF ASTIGMATISM CORRECTION METHODS

The complications associated with incisional keratotomy may be categorized into those that are self-limited side effects, those that occur

### BOX 3.8.1 Potential Complications of Astigmatic and Radial Keratotomy

#### Self-Limited

- Halo effect
- Starburst effect
- Diurnal visual fluctuation
- Early regression

#### Intraoperative

- Marking
  - inaccurate visual axis marking
- Incisions
  - incision invading optical zone
  - incision beyond clear cornea
  - intersecting incisions
- Perforations
  - corneal perforation
  - lens capsule perforation
- Associated with retrobulbar anesthetic
  - optic nerve damage
  - globe penetration/retinal detachment
- Miscellaneous
  - diamond blade chip

#### Postoperative

- Non-sight-threatening complications related to refractive changes
  - undercorrection
  - overcorrection
  - regression
  - progression
  - induced irregular astigmatism
- Miscellaneous non-sight-threatening complications
  - contact lens intolerance
  - epithelial basement membrane disorders
  - epithelial inclusion cysts
  - foreign particles within grooves
  - epithelial iron lines
  - diminished corneal strength
  - endothelial cell loss
- Sight-threatening complications
  - stromal melting
  - infectious keratitis
- Therapy-related
  - Pharmacological
    - drug toxicity
  - Chronic corticosteroid use
    - cataracts
    - glaucoma
  - Contact lens wear
    - keratitis
    - neovascularization
    - late progression of effect
  - Retrobulbar injection
    - optic atrophy
    - globe penetration/retinal detachment

intraoperatively, those that occur postoperatively, and those that are associated with adjunctive therapy (Box 3.8.1).

A number of potential complications may develop intraoperatively as a result of deviations from prescribed surgical protocols or faulty surgical technique. Such complications can generally be avoided by diligent training, literature review, detailed preparation, and adherence to proper surgical protocols. In the unusual event that a complication does occur, sound judgment generally can remedy the problem.

## Complications Related to Corneal Incisions

### Incision Beyond Clear Cornea

Extension of incisions beyond the clear cornea onto the corneoscleral limbus or onto limbal vascular arcades must be avoided to prevent subsequent vascular ingrowth. Incisions that invade the limbus may render the patient intolerant to subsequent contact lens use because of the associated vascularization of the incision grooves. Fibrovascular ingrowth may result

**Fig. 3.8.2 Corneal Perforation.** The risk of corneal perforation has been minimized greatly through recent developments (see text). The horizontal slit shows mild leakage of fluorescein.

in corneal destabilization over time, with large diurnal fluctuation and progression of refractive effect.

### Optical Zone Invasion

Optical zone invasion as a result of spontaneous patient eye movement or lack of surgical control represents one of the more worrisome potential complications of centripetal incisions. Patient education or globe fixation may reduce—but not entirely eliminate—the potential for optical zone invasion. The combined (Genesis) incision technique was designed to address this and other potential complications. Because the uphill margin of the blade cuts only along its distal portion, the diamond cannot produce deep incisions outside the previously incised groove. Once the central zone has been reached and intentionally slightly undermined, continued pressure must not be applied against the optical zone as the diamond is lifted from the groove.

### Complications Related to Corneal Perforations

The risk of corneal perforation (Fig. 3.8.2) has been reduced with the advent of screening and real-time pachymetry, the availability of microscopes for precise diamond knife calibration, and the adherence to protocols suggesting incision of the thinnest corneal zones first and the use of diamonds not set at substantially more than 100% of paracentral pachymetry. The use of the femtosecond laser for AK reduces the complications related to corneal perforations, although it does not eliminate them entirely. The best way to prevent the development of a self-sealing perforation into a more serious perforation is to operate on a relatively dry field so that any leakage of aqueous humor is detected readily.

Early recognition of a self-sealing perforation, by operating on a relatively dry field (no tear pooling within the cul-de-sac), prevents its extension into a nonsealing perforation. Patients who have self-sealing perforations are managed using cycloplegia (for dilatation and prevention of iris adherence to the self-sealing perforation site), topical aqueous suppressants such as beta-blockers, a loading dose of topical antibiotics such as polymyxin and ofloxacin every 5 minutes for three doses, and an ocular shield over the eye. The eye must not be patched, as this compresses the corneal apex, bows open the incisions, and retards healing. The use of collagen shields is not recommended. Incision of the thinnest quadrant first greatly reduces the risk of a self-sealing perforation, as the cornea continues to thin throughout the procedure. If the diamond penetrates the globe on the first incision or on the centrifugally directed component of any incision, the operation may be terminated and completed at a later time, with repeated pachymetry and diamond calibration. The surgeon cannot determine intraoperatively the degree to which the diamond has been overextended or whether pathological corneal thinning exists.

In the event of a nonsealing perforation, it is prudent to place a single (or multiple) interrupted 10-0 or 11-0 nylon suture to seal the wound and prevent any of the sequelae of hypotony or of an open wound.

Early detection of the corneal perforation is important. When a perforation occurs, air bubbles, indicating the invasion of endothelium and/or epithelium integrity, can typically be observed in the anterior chamber.<sup>22</sup> Care should be taken because sometimes the perforation can go undetected, which may lead to postoperative corneal infection and/or endophthalmitis.

**Fig. 3.8.3 Fibrovascular Tracks.** The postoperative development of fibrovascular tracks within incision grooves is most often associated with chronic irritation or hypoxia.

## Postoperative Complications

### Progressive Hyperopia

Risk factors associated with postoperative progressive hyperopia include multiple enhancement procedures, peripheral redeepening procedures, lack of preoperative cycloplegic refraction (latent hyperopia), postoperative contact lens wear, and postoperative ocular massage. The surgeon may wish to consider these factors when patient management strategies are determined.

### Induced Astigmatism

Induced regular or irregular astigmatism may occur if fewer incisions are placed, if the incisions are placed asymmetrically about the visual axis or are of variable depth, or if the optical zone is decentered with respect to the visual axis. The great majority of these refractive aberrations are self-limited and spontaneously improve within the first 6 postoperative weeks. Thus wait until the refraction and surface topography have stabilized before placing additional incisions.

### Contact Lens Intolerance

Newly designed rigid, gas-permeable lenses that have peripheral curves to match the patient's preoperative parameters are recommended to overcome postoperative lens intolerance. The risk of lens-associated corneal vascularization is reduced by a shorter incision that does not extend to the limbus. The fibrovascular tracks within the incision sites are associated most often with chronic irritation and hypoxia from subsequent soft contact lens wear (Fig. 3.8.3). To diminish the risk of this complication, RK incisions are stopped approximately 1 mm short of the limbus. Chronic contact lens wear may provide a direct compressive effect, with associated wound stretching and progressive hyperopia.

### Stromal Melting

Stromal melting often develops in patients who have crossed incisions. Thus this complication can be prevented by taking great care to avoid crossed incisions during surgery. Corneal stromal melt is also associated with patients who have rheumatoid arthritis or other collagen vascular diseases and concomitant severe keratoconjunctivitis sicca with diffuse punctate epitheliopathy (Fig. 3.8.4). Patients affected by such advanced disease are not viable candidates for incisional keratotomies. For patients who have significantly diminished tear production, it may be necessary to perform punctal occlusion before considering incisional keratotomy.

### Infectious Keratitis

Although its incidence is lower than that observed in contact lens wearers, this disorder generally develops in the perioperative period, although delayed cases in association with contact lens wear have been reported. Indeed, the only two cases of keratitis reported in the PERK study<sup>23</sup> occurred in association with postoperative contact lens wear.

Intensive, broad-spectrum antibiotic therapy is instituted. An aggressive protocol may include fortified cefazolin (50 mg/mL), fortified tobramycin (14 mg/mL), and fourth-generation fluoroquinolone—gatifloxacin on an hourly basis, with rotation every 20 minutes, while waiting for culture

**Fig. 3.8.4 Chronic Stromal Melting.** Serious complications as a result of chronic stromal melting may occur in the setting of crossed incisions.

results. A combination of 0.4 mL cefazolin (250 mg/mL) and 0.4 mL tobramycin (40 mg/mL) mixed with 0.1 mL lidocaine 2% may be administered further as a subconjunctival injection to the affected quadrant on a daily basis until culture results are available.

## CONCLUSIONS

The use of incisional keratotomy has declined over the past decade as laser vision correction has gained popularity (due to superior predictability). RK was the most common form of surgical correction of myopia from the 1970s through the early 1990s. It was an important milestone in the history of refractive surgery. In the early 1990s, at the 10-year follow-up of the PERK study, concerns arose about the lack of predictability and stability of RK. There were no identifying risk factors to predict those at risk for the hyperopic shift and the diurnal change in refraction. This is in contrast to the safety, efficacy, and predictability of excimer laser ablation. Incisional keratotomy continues to be an important surgical method for correcting high astigmatism, which, for example, may occur iatrogenically

after penetrating keratoplasty or for the correction of smaller degrees of astigmatism within the framework of cataract surgery. The use of the femtosecond laser to create AK incisions has increased the applicability of AK to correct high and asymmetrical astigmatism, singly or in conjunction with other procedures, although the combined therapy outcomes need to be explored further.

# Intrastromal Corneal Ring Segments and Corneal Cross-Linking

3.9

Claudia E. Perez-Straziota, Marcony R. Santhiago, J. Bradley Randleman

## Definitions:

- Corneal cross-linking (CXL) is a procedure combining corneal saturation with riboflavin and exposure to UV light to increase the amount of links between collagen fibers in the corneal stroma, thereby increasing its tensile strength.
- Intracorneal ring segments (ICRS) are semi circularly shaped polymethyl methacrylate (PMMA) segments that are inserted into the paracentral region of the anterior corneal stroma to flatten the center of the cornea and induce a hyperopic shift.
- CXL is used to halt progression of corneal ectasias, whereas ICRS are used in patients with moderate to advanced stable keratoconus to counterbalance the myopic shift induced by corneal steepening.

## Key Features

- Preoperative evaluation and topographical assessment is necessary to select the appropriate ICRS size and positioning.
- The flattening effect of ICRS can be potentiated by the combination with cross-linking.
- Careful selection of patients for combined ICRS and CXL is imperative to increase the chances of success and reduce the risk of postoperative complications.
- There is currently no consensus regarding timing of combined procedures. Inserting the ICRS before CXL may optimize the impact of ring segment insertion, whereas CXL alone may be sufficient to halt progression and improve corneal shape, thereby obviating the need for a combined procedure.

## INTRODUCTION

For the majority of patients seeking refractive surgery, the best, most effective treatment will be laser ablation as highlighted in the previous chapters. However, for patients with ectatic corneal disease, ICRS and CXL play a prominent role in halting disease progression and improving acuity.

## INTRACORNEAL RING SEGMENTS

Intracorneal ring segments add volume peripherally by changing the arc length of the anterior corneal curvature and redistributing the posterior corneal tissue.<sup>1</sup> This shortens the posterior lamellae and flattens the cornea centrally, correcting myopia.<sup>2,3</sup>

Intracorneal ring segments received European Conformité Européenne certification in 1996 and US Food and Drug Administration (FDA) approval in 1999. However, the initial enthusiasm for the correction of myopia faded due to a limited range of correction, less predictability, induced astigmatism, and slower visual recovery.

The idea of using intrastromal rings in the treatment of keratoconus was proposed in 2000 by Colin et al.<sup>4</sup> Since then their use has evolved into an important therapeutic intervention in corneal ectatic diseases.<sup>4,5,6</sup> Intacs received FDA approval for the use in the treatment of keratoconus in 2004 for rings 0.25–0.35 mm and in 2010 for 0.4–0.45 mm.

In patients with ectatic disease, ICRS induce morphological changes by flattening the steepest meridian and decreasing the cone location magnitude index (CLMI) and the mean curvature in the 2-mm area over the cone. They do not induce significant changes in biomechanical corneal

parameters such as corneal hysteresis and corneal resistance factor, and in younger patients ICRS outcomes have regressed in long-term follow-up,<sup>7</sup> suggesting the underlying biomechanical failure in keratoconus has been left untreated.

## Corneal Cross-Linking (CXL)

In 1998, Spoerl et al. published their findings after collagen cross-linking of porcine corneas, establishing riboflavin as a safe and effective component of the treatment.<sup>8</sup> The first clinical results after CXL in human keratoconic corneas were published in 2003.<sup>9</sup> In the photochemical reaction, riboflavin acts as a photosensitizer that absorbs UV-A energy and excites into a triplet state. This triplet can undergo an aerobic (type 2) or anaerobic (type 1) reaction, both of which create oxygen species that induce covalent bonds between collagen molecules and between proteoglycans and collagen. The depth of this effect is thought to be seen in the demarcation line on optical coherence tomography (OCT) images of post-cross-linking corneas, usually at 300–350  $\mu\text{m}$  of depth.<sup>10</sup> Long-term follow-up of cross-linked corneas has demonstrated that in contrast to ICRS, CXL affects the biomechanical properties of the cornea and halts the progression of the disease with only mild and refractive changes.

## CXL Plus

The lack of significant refractive impact of CXL stimulated the development of treatment protocols combining CXL with a variety of techniques (CXL Plus), including phakic intraocular lens (IOL) implantation and selective excimer laser ablation and CXL combined with ICRS.<sup>11–15</sup>

The rationale behind the combination of ICRS and CXL seems to be the symbiosis that occurs when combining the mechanical and refractive changes induced by the segments with the biomechanical changes induced by CXL and their benefits in halting disease progression.

## SURGICAL PROCEDURE: ICRS

### Patient Selection

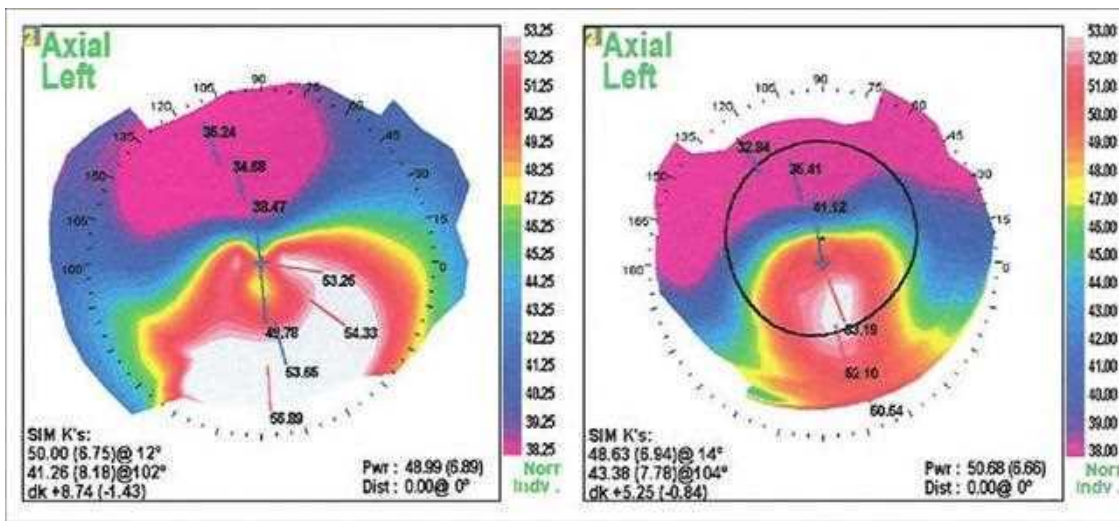

The primary indication for ICRS implantation in ectatic patients include moderate to advanced stages of disease, with clear corneas and unsatisfactory corrected near visual acuity (CDVA) or contact lens intolerance,<sup>16</sup> steepest keratometry less than 58 diopters (D), no corneal scarring or opacities, and at least 450  $\mu\text{m}$  thickness at the 7-mm diameter where the segments are to be placed.<sup>17</sup> The flattening effect of ICRS becomes more robust in advanced stages of ectasia.

### Preoperative Considerations

Preoperative refraction, aberrometry, and corneal topography are important factors to consider in surgical planning. Topographical features are relevant in the selection of the segments and their location in asymmetrical corneas, with thicker and longer segments placed in the area just below the cone. Single versus paired segment implantation appear to be equivalent in terms of refractive results,<sup>18</sup> and the decision should be made on a case-by-case basis using the manufacturer's ICRS nomograms.

### ICRS Selection

There are currently three main types of ICRS: **Intacs** (Addition Technology, Sunnyvale, CA), with a hexagonal transverse shape, and **Intacs SK**, with

**Fig. 3.9.1 Topographical Flattening After Intacs Segment Placement.**  
 Note the reduction in size and maximal steepness in the right image (after segment implantation) compared with the left image (before segment implantation).

an oval cross-section shape; **Ferrara**, with triangular shape, and **Keratings** (both from Mediphacos, Belo Horizonte, Brazil), with almost identical design to Ferrara rings, but different arc lengths and internal diameters. Intacs are the only FDA-approved ICRS for the reduction or elimination of myopia and astigmatism in normal patients or those with keratoconus and are available in 0.25, 0.30, and 0.35 mm. The 0.4-mm Intacs and the Ferrara rings are available only in European countries and South America. The effect of the implantation of an ICRS correlates directly to its thickness and inversely to its distance from the visual axis, or *optical zone*, with thicker implants and smaller optical zones resulting in greater flattening effect and reduction of coma-like aberrations.<sup>1,19,20</sup>

### Single Versus Paired ICRS

In cases of peripheral steepening, where the main issue is irregular astigmatism, implanting a single segment may provide better results than two segments, whereas in central cones, where the high myopic refractive error is the main issue, two segments or a longer continuous segment with a simple nomogram using keratometry readings only are a better alternatives because they target a larger change in spherical equivalent.<sup>21–24</sup>

### ICRS Surgical Technique

Intrastromal corneal ring segments are placed within the peripheral stroma at approximately two-thirds of the stromal depth, outside the central optical zone, to reshape the anterior corneal surface while maintaining the positive asphericity of the cornea.<sup>25–32</sup>

There are no significant differences in refractive outcomes of ICRS between femtosecond laser and manual spreader. When using femtosecond laser, the efficacy in creation of an intrastromal channels can be affected by previous cross-linking treatment, perhaps due to changes in the optical quality of the anterior stroma that interfere with laser tracking. Therefore even though femtosecond laser is associated with fewer complications compared with the mechanical spreader,<sup>33</sup> manual dissection of the channels may be considered in patients that have been previously cross-linked.

After channel formation, the segments are introduced with forceps into the channels. In their final position, the segments should be located 3 mm apart superiorly. Once the segments have been inserted, each segment has a small positioning hole at the superior end to aid with surgical manipulation for proper positioning, after which the incision site is hydrated and closed with 10–0 nylon sutures.<sup>25</sup>

### Clinical Outcomes

ICRS flatten the cornea permanently, but the major shifts in refraction and topographical findings after ICRS implantation usually occur in the first 6 months of postoperative period<sup>34</sup> with some fluctuations during the first month (Fig. 3.9.1). Even though late postoperative variations probably occur due to intrinsic biomechanical changes in those with unstable disease, the difference in CDVA and keratometry between month 6 and month 36 is not significant.

The results of ICRS in patients with corneal ectasia are encouraging, especially in decreasing astigmatism and improving topographical

**Fig. 3.9.2 Late-Onset Corneal Haze After Intracorneal Ring Segment Implantation.**

abnormalities, with reported significant changes in spherical equivalent (SE), (average 4.0 D reduction in SE), manifest astigmatic error and UCVA, with the most significant improvement in the first 6<sup>4</sup> and 9 months.<sup>5,6</sup>

### Postoperative Complications

The overall reported adverse event rate after ICRS is 1.1% including infectious keratitis (0.2%), shallow placement (0.2%), loss of two lines of best spectacle-corrected visual acuity (BSCVA) (0.2%), and anterior chamber perforation during initial and exchange procedures (0.4%).<sup>35,36</sup> Reduced central corneal sensation can occur up to 6 months after surgery and can persist up to 12 months in 5.5% of cases. Some patients experience difficulty with night vision (4.4%), blurry vision (2.9%), diplopia (1.6%), or glare and halos (1.3%),<sup>35</sup> which accounts for an explantation rate of 8.7%, mostly due to glare, halos, and difficulty with night vision as well as dissatisfaction with refractive results. Late onset corneal haze is another potential complication (Fig. 3.9.2).

### SURGICAL PROCEDURE: CXL

The procedure for CXL involves three essential steps: epithelial removal (9 mm debridement), riboflavin saturation of the corneal stroma, and stromal irradiation with UV-A light (Fig. 3.9.3). These elements can be combined in varying intensities and times. For CXL, after complete UVA irradiation, a bandage soft contact lens is typically placed and left in place until complete epithelialization is achieved.

**Fig. 3.9.3 Corneal Cross-Linking Procedure.** After riboflavin saturation, the cornea is exposed to UV-A light. The red lines are guidance beams to ensure proper treatment centration.

**Fig. 3.9.4 Corneal Demarcation Line Following CXL With the Standard Protocol.** Note the prominent demarcation line at approximately 300  $\mu\text{m}$  depth.

The **standard protocol** delivers 3  $\text{mW}/\text{cm}^2$  of energy for 30 minutes for a total energy dose (fluence) of 5.4  $\text{J}/\text{cm}^2$ , resulting in up to 70% increase in cornea rigidity compared with controls using porcine and human cadaver eyes.<sup>8,37</sup> **Accelerated protocols**, still with a total dose of 5.4  $\text{J}/\text{cm}^2$ , have been derived from the Bunson–Roscoe law of reciprocity of photochemistry, which states that the photochemical effect of ultraviolet light is proportional to the total amount of energy delivered and should be equivalent for equivalent total doses regardless of the relative irradiation time and intensity for each protocol.<sup>38</sup> These accelerated protocols have been evaluated with mixed results.

The demarcation line, evident after cross-linking with the standard protocol (Fig. 3.9.4) and typically approximately 300  $\mu\text{m}$  deep, is thought to represent the depth of cross-linking treatment and thereby serves as a surrogate of biomechanical impact.<sup>39–44</sup> In accelerated protocols and iontophoresis CXL, the demarcation line is less dense, less uniform, and demonstrably present in fewer cases.<sup>40,45,46</sup> Recently a modified accelerated protocol of 9  $\text{mW}/\text{cm}^2$  for 14 minutes has been proposed by Kymionis and colleagues with no difference in the demarcation line compared with standard CXL protocol.<sup>44</sup>

**Transepithelial (epi on) CXL** has also been reported, but while corneal confocal microscopy alterations are similar in the subbasal nerve plexus and anterior stromal keratocytes between standard and accelerated (30  $\text{mW}/\text{cm}^2$  for 3 minutes) protocols, no changes are seen after transepithelial approaches.<sup>47</sup> Effective riboflavin concentration seems to be

achieved only when corneal epithelium is removed.<sup>48</sup> To date, long-term clinical results of transepithelial CXL have failed to find equivalency with the standard protocol.

## CXL CLINICAL OUTCOMES

Results from the first US-based prospective clinical trial for cross-linking demonstrated improvement in visual acuity and reduction in Kmax in patients with ectatic disease either LASIK induced or from keratoconus, with greater flattening in keratoconus compared with post-LASIK ectasia patients.<sup>49</sup> These changes continued over time, resulting in progressive improvement of uncorrected and corrected distance visual acuities and reduction in higher order aberrations up to 4 years postprocedure, which do not necessarily correlate with the topographical changes observed.<sup>50</sup> Failure to halt progression has been seen in approximately 2%–4% of eyes treated, with up to 2% of eyes losing lines of Snellen visual acuity.<sup>51</sup> These failures were initially associated with older age (beyond 35 years old), thinner corneas (<400  $\mu\text{m}$ ), preoperative CDVA better than 20/25, and Kmax >58.00 D. These risk factors were not confirmed in prospective trials.

## Postoperative Complications

UV light can have deleterious effects *within* the corneal stroma. Standard epi-off riboflavin/UVA treatments trigger a temporary UVA dose-dependent keratocyte apoptosis response approximately at 300  $\mu\text{m}$  deep that typically resolves with nerve regeneration and stromal keratocyte repopulation 4–6 weeks after the procedure. Endothelial damage is possible, but avoidable by maintaining a safe stromal thickness of 400  $\mu\text{m}$  during treatment. Monitoring corneal thickness throughout the procedure with use of iso-osmolar riboflavin solution to minimize stromal thinning along with use of hypo-osmolar riboflavin solutions to temporarily thicken the cornea all reduce the risk of endothelial cell damage in patients with thinner corneas.

The corneal wound-healing process after epithelial removal increases the risk of delayed re-epithelialization, sterile and infectious stromal infiltrates, corneal haze, and scarring. Matrix metalloproteinases (MMPs)-mediated activation of keratolysis, caused by nonsteroidal anti-inflammatory drugs (NSAIDs), also can induce corneal melting. For this reason the use of NSAIDs in the early postprocedure period after CXL is controversial. The disruption of corneal epithelium also increases the risk of infectious keratitis. CXL may lead to the reactivation of herpes simplex keratitis. Sterile stromal infiltrates rarely occur; these usually are asymptomatic and not visually significant. Persistent stromal haze correlated with advanced keratoconus (steeper keratometric values and/or thinner corneas) and older age (beyond 35 years old) at the time of treatment can become visually significant and affect final outcomes after CXL.

## COMBINING ICRS WITH CXL

Due to potential optical changes in the corneal stroma after CXL that could interfere with laser tracking, inserting the ICRS *before* CXL when using the femtosecond laser appears optimal. Refractive outcomes appear better when ICRS are implanted before cross-linking, possibly due to reduced mechanical effect from ICRS after CXL, but some concerns remain about the impact of CXL on the PMMA material of the ICRS.

Timing of treatment is undetermined, with some advocating for waiting 3–6 months between treatments, while others advocate for implantation of ICRS with intrastromal injection of riboflavin through the ring channels, followed immediately by CXL treatment.<sup>52</sup> Comparative studies are warranted to determine whether simultaneous treatments are superior to sequential treatments.

## CONCLUSIONS

Epithelium-off CXL using the standard protocol has been proven to effectively flatten the steepest regions of the cornea in patients with progressive ectatic disease, halting the progression of disease, reducing the need for corneal transplantation, and improving visual acuity and quality of life. ICRS also play a role in management of ectatic corneal disease, with surgical techniques advancements resulting from the advent of the femtosecond laser. The preservation of the prolate cornea and the reversibility of the procedure are major advantages of ICRS implants, and their mechanical effect can have a symbiotic effect with CXL.

# Surgical Correction of Presbyopia

Veronica Vargas Fragoso, Jorge L. Alió

3.10

**Definition:** Presbyopia is an age-related condition that enables the patient to perform near visual tasks due to the decay of accommodation.

Key Features

- Presbyopia starts affecting people around 40 years of age.
- Its surgical correction may be performed at the cornea, lens, or sclera.
- Corneal procedures like monovision have good visual outcomes, but some stereopsis may be lost.
- Multifocal intraocular lenses (IOLs) have a high rate of spectacle independence, but the appearance of glare and halos are an important drawback.
- Not all commercially available accommodative IOLs have proved to really restore accommodation.
- Surgical correction of presbyopia with the restoration of accommodation is still a challenge for all refractive surgeons.

INTRODUCTION

Presbyopia is an age-related condition characterized by the loss of accommodation, enabling the patient not to perform near visual tasks, decreasing the quality of life.<sup>1</sup>

Its correction remains a challenge for the refractive surgeons; although many procedures to restore near vision are available, not all of them really restore accommodation (with the exception of some accommodative IOLs).

Accommodation is the change of power of the crystalline lens that allows us to change the point of focus from far to near.

During accommodation, there is a contraction of the ciliary muscle, which releases the zonular tension, allowing the anterior and posterior surfaces of the lens to increase in curvature, increasing the optical power of the lens (Helmholtz theory).

This is accompanied by the accommodative triad: accommodation, convergence, and miosis,<sup>2</sup> and there is also an increase in negative aberration of the eye.

Most of the presbyopia treatments induce pseudo-accommodation, which improves near vision through multifocality or increasing the depth of field, not by a change of the optical power of the eye sustained by the active action of the ciliary body.<sup>2</sup>

Presbyopia can be corrected at the cornea, lens, or sclera or treated with topical medication; all therapeutic options come with pros and cons.

In this chapter, we will discuss all of the current treatment options for presbyopia correction.

PRESBYOPIA CORRECTION AT THE CORNEAL LEVEL

Correction at the cornea can be achieved by monovision, presby-LASIK, and corneal inlays.

Monovision

Correction with monovision was first described in 1958 by Westsmith with contact lenses wearers.<sup>3,4</sup>

It can be achieved through contact lenses, LASIK, or pseudo-phakia.

In monovision, an intended anisometropia is induced in order to provide near and distance vision. Usually, the nondominant eye is corrected for near vision and the dominant eye for far vision. This is because

TABLE 3.10.1 Advantages and Disadvantages of LASIK Monovision

Advantages	Disadvantages
Good far and near outcomes	Reduction of stereopsis
Reversible	Slight reduction in contrast sensitivity
Easy to perform surgically	Not all patients are good candidates
	Asthenopia

monovision depends on interocular blur suppression, and an assumption exists that it is easier to suppress blur in the nondominant eye.<sup>4,5</sup> However, pseudo-phakic crossed monovision (nondominant eye is corrected for far and the dominant eye for near vision) has had similar outcomes to conventional monovision.<sup>3,4</sup>

There is a correlation between the degree of anisometropia and the improvement of near and intermediate distance acuity; the greater the anisometropia, the better the near visual outcome.<sup>6</sup> At the same time, the greater the anisometropia, the greater the loss of stereopsis.<sup>6,7</sup> Also, an increased time for neuroadaptation is required,<sup>7</sup> and a major risk for monofixation syndrome (loss of foveal fusion which manifests as a facultative absolute scotoma in the fovea of the nonfixating eye) exists.<sup>8</sup> Thus, the anisometropia should not be more than 1.5 diopters (D) because it has been reported for good spectacle independence in patients with mini-monovision, in which the target for the nondominant eye is -1.00 to -1.25 D and that for the dominant eye is plano.<sup>9</sup> In this way, stereopsis is maintained.

Patient selection is important as in every other surgical procedure, and monovision is generally contraindicated for the following patients: airplane pilots,<sup>3,10</sup> truck or taxi drivers,<sup>6,10</sup> and patients with strong ocular dominance,<sup>3,11,12</sup> strabismus,<sup>3,12</sup> or exophoria of more than 10.0 Δ.<sup>3,4,6,10</sup>

Good near and distance outcomes have been reported for LASIK monovision. Spectacles for night driving were used in only 16.2% of patients, and there was a slight decrease in contrast sensitivity and stereopsis<sup>13</sup> (Table 3.10.1).

Pseudo-phakic monovision has a success rate of approximately 80%,<sup>12,14</sup> and the advantage over multifocal IOLs is the lower cost.<sup>14</sup> Although the rate of spectacle independence is higher with multifocal IOLs, they induce more dysphotopsia.<sup>15a</sup>

Monovision is one of the most popular presbyopia treatments among refractive surgeons; it also offers the possibility of reversal in case of patient dissatisfaction. LASIK monovision is ideal for presbyopic patients over 40 years of age, and in pseudo-phakic monovision for patients with cataract in whom a multifocal or accommodative IOL is contraindicated.

Presby-LASIK

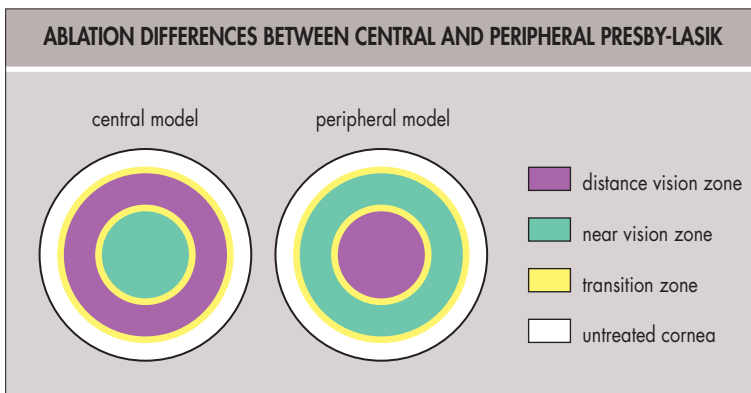

Presby-LASIK is a surgical technique that employs the principles of LASIK to create a multifocal corneal surface.

There are three main types of multifocal corneal excimer laser profiles: (1) multifocal transition profile (no longer in use because it induced significant levels of vertical coma), (2) central presby-LASIK, and (3) peripheral presby-LASIK (Fig. 3.10.1). The principles of each algorithm are based on the dioptric power of refractive error and presbyopia correction calculation, corneal asphericity quotient (Q-value), and changes in higher-order spherical aberrations or optical and transition zone manipulation.

Central Presby-LASIK

This technique was first described by Ruiz in 1996.<sup>15b</sup> It creates a hyper-positive area for the near vision at the center, and the periphery is left for far vision.

**Fig. 3.10.1 Ablation Differences Between Central and Peripheral Presby-LASIK.** In the peripheral model, the center of the cornea is modified for distance vision; in the central model, the center of the cornea is modified for near vision.

It is pupil dependent, and an advantage is that it can be performed at the center of the cornea in myopic and hyperopic profiles as well as in emmetropes with minimal corneal excision. Adequate centration is crucial for having a controllable result.

Its main limitation is the lack of adequate alignment among the line of sight, the central pupil, and the corneal vertex, which leads to the induction of coma aberrations.

These are the platforms available for central presby-LASIK:

- **AMO VISX** hyperopia-presbyopia multifocal approach steepens the central zone to improve near vision and the peripheral zone for distance vision. It is for hyperopic patients with astigmatism up to +4.00 D and -2.00 D.
- **SUPRACOR** (Technolas Perfect Vision GmbH, Munich, Germany) is an aberration-optimized presbyopic algorithm. The SUPRACOR creates a hyperpositive area in the central 3.0 mm zone, and the treatment targets 0.50 D of myopia in both eyes.<sup>16</sup> It treats hyperopic presbyopia and minimizes the aberrations normally induced during treatment.
- **PresbyMAX** (SCHWIND eye-tech-solutions GmbH, Kleinostheim, Germany, Dr Jorge Alió's trademark) is based on the creation of a biaspheric multifocal corneal surface with a central hyperpositive area to achieve +0.75 to +2.50 D of near vision correction, surrounded by an area in which the ablation is calculated to correct the distance refractive error.<sup>17,18</sup> It can be performed in hyperopes and myopes.
- In **peripheral presby-LASIK**, the center of the cornea is left for distance and the periphery is ablated in a way that a negative peripheral asphericity is created to increase the depth of field.

However, when positive spherical aberration is present, if the pupil becomes miotic, the refraction of the eye experiences a shift toward positive spherical values.

One of its disadvantages is that when it is used in association with myopic correction, it is necessary to remove a significant amount of corneal tissue. This is why it is mainly done in hyperopes. It also requires an efficient excimer laser beam profile that can compensate for the loss of energy that happens while the peripheral cornea is ablated. This is one of the main difficulties in targeting specifically high negative asphericity values with this technique. A relatively flatter central cornea and more highly curved corneal midperiphery were described by Avalos (PARM technique), and a proprietary peripheral presby-LASIK algorithm was described and patented by Tamayo.

## Laser Blended Vision

This technique combines a low degree of asphericity and micromonovision in the near eye to achieve good near and distance vision.<sup>19</sup> A sphericity between -0.58 and -0.70 is created to increase the depth of field.

Reinstein et al.<sup>19</sup> reported good visual outcomes with this technique, achieving binocular visual acuity of 20/20 at distance and J3 at near in 99% of patients. These hybrid techniques combine the best features of the multifocal cornea and monovision, achieving good visual outcomes.

The rates of spectacle independence with central presby-LASIK vary from 72%<sup>20</sup> to 93%.<sup>16</sup> A loss of corrected distance visual acuity (CDVA) of at least one line has been reported with central<sup>16,21-25</sup> and peripheral<sup>26-28</sup> presby-LASIK.

The main disadvantage of presby-LASIK is the lack of long-term results (beyond 3-year outcomes), and having a multifocal cornea can be a limitation for further multifocal IOL implantation.

## Intracorneal Inlays

### Historical Background

In 1964 Barraquer developed keratophakia, a lamellar refractive procedure in which an alloplastic lenticule is placed at the interface of the free corneal cap and the stromal bed.<sup>29a</sup> The difficulty of the surgical procedure and the unpredictability of the refractive results meant that few surgeons adopted keratophakia.<sup>29b</sup>

Early corneal implants were made of polymethylmethacrylate or polysulfone, and although they corrected the refractive error, they produced corneal necrosis and implant extrusion.<sup>30</sup> Nowadays, the material used in corneal inlays allow sufficient nutrient flow; a very important feature because interruption of the nutrient flow can cause loss of transparency, corneal thinning, epithelial and stromal decompensation, and melting.<sup>31</sup> The permeability of the hydrogel material used in the inlays is similar to that of the corneal stroma, allowing to some extent the exchange of nutrients<sup>32,33</sup> such as glucose and oxygen.

Corneal inlays have several advantages: There is no need to remove corneal tissue, the surgical technique is relatively easy and minimally invasive, and the inlays are all removable.<sup>9,34,35</sup>

There are three types of corneal inlays<sup>9,34</sup>:

- **Corneal reshaping inlays**  
They enhance near and intermediate vision through a multifocal effect. There's a reshape of the anterior curvature of the cornea (hyperprolate region of increased power).<sup>34,35</sup>
- **Refractive inlays**  
An alteration of the refractive index occurs with a bifocal optic.<sup>34</sup>
- **Small aperture inlays**  
There is an improvement of depth of focus.<sup>34</sup>

The inlays are implanted in the nondominant eye within a corneal pocket made by a femtosecond laser or under a stromal flap (the pocket is preferred because it might decrease the incidence of dry eye).<sup>31</sup> The depth depends on the inlay.<sup>35</sup> Inlays that alter the curvature of the cornea are implanted more superficially; inlays with small aperture or those that have a different index of refraction are implanted deeper to avoid changes in the cornea curvature and to allow a proper diffusion of nutrients in the corneal stroma.<sup>31</sup> The inlays must be centered on the first Purkinje reflex.

There are currently four corneal inlays available on the market:

- **KAMRA Vision** (AcuFocus Inc., Irvine, CA, USA). Small aperture inlay.
- **Raindrop** (ReVision Optics Inc., Lake Forest, CA, USA). Corneal reshaping inlay.
- **Flexivue Microlens** (Presbia Cooperatief U.A., Amsterdam, the Netherlands). Refractive inlay.
- **Icolens** (Neoptics AG, Hünenberg, Switzerland). Refractive inlay.

## Corneal Reshaping Inlay

### Raindrop

Formerly known as the PresbyLens or Vue + lens (ReVision Optics, Lake Forest, CA, USA), it's made of biocompatible hydrogel material and 80% water. It has a thickness of 10  $\mu$ m at the periphery and 32  $\mu$ m at the center; the diameter is 2 mm (Fig. 3.10.2).<sup>30</sup> The inlay is permeable, allowing the passage of nutrients and oxygen.<sup>9,34-36</sup> It reshapes the anterior central corneal surface, creating a hyperprolate region, resulting in a multifocal cornea.<sup>36</sup> It has no refractive power.<sup>34,35</sup>

It should be placed in the nondominant eye at a minimum depth of 150  $\mu$ m with a residual stromal bed thickness of 300  $\mu$ m and has to be aligned over the center of the light-constricted pupil.<sup>35-37</sup> The central corneal thickness of the eye should be 500  $\mu$ m or thicker. After the inlay is positioned over the center of the pupil, it has to dry for 30 seconds before the flap is repositioned.<sup>37</sup>

Barragan et al.<sup>30</sup> reported the results of a 1-year follow up using the Raindrop inlay in emmetropic presbyopes. In their study, 100% of eyes achieved an uncorrected near visual acuity (UNVA) of 0.2 logMAR or better in the operative eye, and binocularly, 100% of patients achieved an UNVA of 0.18 logMAR or better. No eye lost two or more lines of corrected distance visual acuity (CDVA) or corrected near visual acuity (CNVA).

Yoo et al.<sup>38</sup> measured the corneal and optical aberrations in 22 emmetropic presbyopes with a mean addition power of  $+1.97 \pm 0.30$  D. All

**Fig. 3.10.2** Raindrop corneal inlay.

patients gained monocular and binocular UNVA. For a 4-mm pupil size, significant increases occurred in total root mean square (RMS), coma-like RMS, and spherical-like RMS. Overall, 82% of the patients were satisfied or very satisfied with their near vision, and 13.6% reported that they needed glasses for near vision more often after surgery than before surgery. Moreover, 37% of patients reported glare. They concluded that the procedure can induce higher-order aberrations (HOA) but had moderate effects on the entire optical system.

In a study by Alió et al.,<sup>33</sup> increases in spherical aberrations, coma, and total HOA were reported with the implantation of hydrogel inlays.

Whitman et al.<sup>39</sup> reported the clinical outcomes with the Raindrop inlay in patients with emmetropic presbyopia. In total, 340 patients completed a 1-year follow-up, and on average, they had an improvement in UNVA of five lines and in uncorrected intermediate visual acuity (UIVA) of 2.5 lines. However, the uncorrected distance visual acuity (UDVA) decreased by 1.2 lines. Contrast sensitivity loss occurred at the highest spatial frequencies with no loss of binocularly. Eighteen inlays were replaced because of decentration, and 11 were explanted (five patients were dissatisfied with their vision, two had inlay misalignment, two had epithelial ingrowth, one had visual symptoms associated with decreased visual acuity, and 1 had recurrent central corneal haze that failed to respond to topical treatment).

### Refractive Inlays

#### Presbia Flexivue Microlens

The Presbia Flexivue Microlens, a transparent hydrophilic concave-convex disc made of a clear copolymer of hydroxyethylmethacrylate and methylmethacrylate with an ultraviolet blocker.<sup>31,36,40</sup> It has a diameter of 3.2 mm and a thickness of 15–20  $\mu\text{m}$ , depending on the additional power. The central 1.8 mm diameter of the disc is plano in power, and the peripheral zone has an add power, ranging from +1.25 D–3.00 D in 0.25-D increments. At the center, there is an opening of 0.15 mm that facilitates the transfer of nutrients and oxygen through the cornea (Fig. 3.10.3).<sup>31,34–36,40</sup> It has a refractive power of 1.4583 and a light transmission of 95% at a wavelength above 410 nm.<sup>36,40</sup>

During distance vision, light rays pass through the central zone of the inlay that does not have refractive power (plano), so they will be sharply focused on the retina. Light rays that pass through the refractive peripheral zone will focus in front of the retina.

During near vision, rays passing through the central zone of the inlay will focus behind the retina, and those passing through the peripheral refractive zone of the inlay will be focused on the retina.<sup>31,40</sup> The rays passing through the peripheral clear cornea will be blocked by the pupil.<sup>40</sup>

It is implanted in the nondominant eye. The corneal pocket is within a depth of 280–300  $\mu\text{m}$ <sup>34,36,40</sup> and is centered over the patient's visual axis based on the first Purkinje reflex. The corneal inlay power is calculated by decreasing the preoperative CNVA manifest refraction SE by 0.25 D.<sup>31</sup>

Limnopoulou et al.<sup>40</sup> reported in their 1-year follow-up study a UNVA of 20/32 or better in 75% of operated eyes; the UDVA decreased significantly in the operated eye from 20/20 to 20/50, but binocular UDVA was not significantly altered. HOA increased and contrast sensitivity decreased in the operated eye. They included 47 emmetropic presbyopes between 45 and 60 years old. No removals of the inlay and no intra- or postoperative complications occurred.

**Fig. 3.10.3 Flexivue Inlay.** (Image from Malandrini A, Martone G, Menabuoni L. Bifocal refractive corneal inlay implantation to improve near vision in emmetropic presbyopic patients. *J Cataract Refract Surg* 2015;41:1962–72.)

**Fig. 3.10.4 Icolens Inlay.** (Image taken from Bailly C, Kohnen T, O'Keefe M. Preloaded refractive-addition corneal inlay to compensate for presbyopia implanted using a femtosecond laser: one-year visual outcomes and safety. *J Cataract Refract Surg* 2014;40:1341–8.)

Malandrini et al.<sup>31</sup> performed a 36-month follow-up study in 26 eyes, and the mean preoperative UNVA and UDVA were 0.76 logMAR and 0.00 logMAR, respectively, compared with 0.10 logMAR and 0.15 logMAR, postoperatively. Overall, 62% of the eyes lost more than 1 line of UDVA, and 19% lost more than two lines of UDVA. Also, 8% of the eyes lost more than 1 line of CDVA at 36 months. The mean spherical aberration increased after surgery. Explantation was performed in six eyes because of reduced UDVA, halos, and glare; 6 months after explantation, the CDVA in all cases had returned to preoperative levels.

#### Icolens (Neoptics AG)

This corneal inlay is made of a copolymer of hydroxyethyl methacrylate and methyl methacrylate. It has a bifocal design with a peripheral positive refractive zone for near vision and a central zone for distance vision.<sup>41</sup> It has a diameter of 3 mm, a peripheral thickness of 15  $\mu\text{m}$ , and a central 0.15 mm hole for nutrient flow (Fig. 3.10.4).<sup>35,41</sup>

Bailly et al.<sup>41</sup> reported the results of the Icolens 12 months after implantation. The inlay was implanted in the nondominant eye of emmetropic

**Fig. 3.10.5 KAMRA Inlay in a Light-Colored Eye.** (Image taken from Abbouda A, Javaloy J, Alió JL. Confocal microscopy evaluation of the corneal response following AcuFocus KAMRA inlay implantation. *J Refract Surg* 2014;30:172–8.)

**TABLE 3.10.2 Inlay Characteristics**

Characteristic	ACI7000 (First One)	ACI7000T	ACI7000PDT (Latest)
Thickness	10 $\mu\text{m}$	5 $\mu\text{m}$	5 $\mu\text{m}$
Holes	1600	1600	8400
Diameter	25 $\mu\text{m}$	25 $\mu\text{m}$	5–11 $\mu\text{m}$

patients through a corneal pocket created by femtosecond laser at a depth of 290  $\mu\text{m}$ ; 52 patients were included. The UNVA improved from N18/N24 preoperatively to N8 postoperatively, with 100% of patients having N16 or better, and nine patients having N5 or better. The mean UDVA in the surgical eye worsened significantly from 0.05 $\pm$ 0.12 logMAR preoperatively to 0.22 $\pm$ 0.15 logMAR postoperatively. There was a loss of CDVA, with 77% of the patients losing more than one line (they believe this was secondary to a neuro-optical phenomenon related to the implant). Seven inlays were removed because of inadequate centration, three secondary to ambiguous ocular dominance, and one because the patient had unrealistic expectation, for a total of 11 inlays removed.

### Small Aperture Inlays KAMRA

The KAMRA inlay (AcuFocus Inc., Irvine, CA, USA) is the most widely used corneal inlay,<sup>35</sup> with nearly 20,000 inlays implanted worldwide.<sup>9,36</sup> It is made of polyvinylidene fluoride. The latest design (ACI 7000PDT) has a 3.8-mm diameter with a central 1.6-mm aperture and a thickness of 5  $\mu\text{m}$ . It has 8400 microperforations ranging in diameter from 5 to 11  $\mu\text{m}$  to allow nutritional flow through the cornea.<sup>9,34–36,42</sup> It also has nanoparticles of carbon, which<sup>43,44</sup> has a light transmission of 5%.<sup>43</sup> Because it is an opaque inlay, it may be visible in light-colored eyes (Fig. 3.10.5).<sup>9</sup>

The KAMRA inlay improves near vision by increasing the depth of focus<sup>35,36</sup> through the principle of small aperture optics. It is implanted in the nondominant eye in a lamellar pocket that is 200–220  $\mu\text{m}$ . Its implantation does not cause scotomas in the visual field.<sup>34</sup> It allows a normal visualization of the central and peripheral fundus and a good quality of central and peripheral imaging and optical coherence tomography (OCT) scans.<sup>45</sup> However, annular shadows visible on the GDx VCC scans have been reported.<sup>46</sup>

The inlay has evolved over the years, with the same artificial aperture of 3.8-mm outer diameter and 1.6-mm inner diameter. Table 3.10.2 describes the inlay characteristics.

Tomita et al.<sup>43</sup> evaluated the outcomes of KAMRA inlay implantation and simultaneous LASIK in hyperopic, myopic, and emmetropic patients. With a 6-month follow-up, they concluded that the procedure was safe and improved distance and near visual acuity. However, postoperative symptoms like halos, glare, and night-vision disturbances were observed.

Igras et al.<sup>47</sup> reported a 1-year follow-up of combined LASIK and KAMRA inlay implantation. Of 132 patients evaluated, 85% were hypermetropic, 11% emmetropic, and 4% myopic. By 12 months, 97% of patients had J3 or better UNVA. Also, 6.3% of patients lost one line of CDVA in the implanted eye, and none lost two or more lines compared with their preoperative VA. Two inlays were explanted, one due to poor night vision and one secondary to persistent hyperopic shift and corneal haze. They concluded that a significant improvement occurred in near visual acuity

**Fig. 3.10.6 Iron Deposits in the Periphery on the Inlay (Red Arrows) and in the Center of the Inlay (Green Arrow).** (Image taken from Dexl AK, Ruckhofer J, Riha W, et al. Central and peripheral corneal iron deposits after implantation of a small-aperture corneal inlay for correction of presbyopia. *J Refract Surg* 2011;27:876–80.)

with a slight compromise in uncorrected monocular distance visual acuity in the implanted eye without a binocular effect on the UDVA.

Seyeddain et al.<sup>46</sup> performed a 3-year follow-up with 32 emmetropic presbyopic patients and reported that although there were significant gains in UNVA and UIVA, 28.3% of patients lost one line of CDVA.

Dexl et al.<sup>48</sup> described iron corneal deposits after implantation of the AcuFocus corneal inlay (ACI 7000) in 18 eyes (56%), but these deposits did not have any influence on distance, near, uncorrected, or corrected visual acuity (Fig. 3.10.6).

Alió et al.<sup>42</sup> reported that after removal of the KAMRA inlay, the topography and aberrometry were not permanently affected, and more than 60% of the patients had a CNVA, CDVA, UNVA, and UDVA similar to their preoperative values. The study involved 10 eyes and had a follow-up of 6 months after the inlay removal. The reason for removal in eight eyes was subjective dissatisfaction with visual symptoms (glare, starburst, blurry vision, and halos). One case was related to an inadvertent thin flap, and the other was related to insufficient near vision.

Abbouda et al.<sup>49</sup> analyzed the corneal tissue appearance 6 months after KAMRA inlay implantation by confocal microscopy; the study included 12 eyes in which one of three models of the KAMRA inlay had been implanted. The epithelial layers appeared normal in all patients. A low grade of keratocyte activation was found in all patients. Few patients had an elevated number of activated keratocytes, and they had a reduction in UNVA (needed reading glasses), CNVA, and CDVA. The UDVA was not affected. Subbasal nerve plexus was detected in 10 patients, and the branch pattern was found in eight patients. Four patients had the inlay explanted, the main reason being subjective dissatisfaction with visual symptoms and poor vision. All of them had a donut appearance at the slit-lamp examination. None of the patients had refractive postoperative changes. They concluded that the corneal tolerance to the inlay is good and that it modifies the normal structure of the corneal layer without associated complications.

Keratocyte activation is an important variable for the refractive outcome after KAMRA inlay implantation; flap thickness depth, low laser energy cut, and topical corticosteroid treatment are helpful to avoid it.

Lin et al.<sup>50</sup> compared the contrast sensitivity before and after implantation of the KAMRA inlay in 507 patients. They reported that postoperatively contrast sensitivity was mildly reduced monocularly but not binocularly, and that it remained within the normative ranges.

This inlay can be implanted also in patients with previous cataract surgery who have a monofocal IOL, as reported by Huseynova et al.<sup>51</sup> They implanted the KAMRA inlay in 13 pseudo-phakic patients with a monofocal IOL. Four patients had LASIK at the time of the inlay implantation. There was no change in mean UDVA after the inlay implantation, and the mean UNVA improved by five lines. Three eyes lost two lines, and one eye lost one line of UDVA. Two eyes lost two lines, and one eye lost one line of CDVA (Table 3.10.3, Table 3.10.4, Fig. 3.10.7).

## Presbyopic IOLs

Correction of presbyopia with premium IOLs has been the best option, because they provide good distance and near visual outcomes and spectacle independence. However, perfection has not been achieved with these IOLs, which can be divided in two main groups, multifocal IOLs and accommodative IOLs.

### Multifocal IOLs

The perfect multifocal IOL must provide excellent near, intermediate, and distance visual acuity; should not produce photic phenomena; and should be pupil independent. The design has to be aspherical and able to be implanted through a small incision to allow the performance of micro incision cataract surgery (<2 mm). Sadly, there is no single multifocal IOL that can provide all these factors at the same time.

The aim of these IOLs is to provide patients with spectacle independence for both near and distance vision through the division of the incoming light into two or more foci<sup>52–55</sup> independently of capsular mechanics and ciliary body function.<sup>56</sup>

Multifocal IOLs can be divided based on their design as rotationally symmetrical IOLs (which can be further divided as: diffractive, refractive, or a combined design) and rotationally asymmetrical IOLs (also called varifocal IOLs).<sup>53–57</sup>

### Rotationally Symmetrical

**Diffractive IOLs.** These IOLs have in them surface rings that form a discontinued optical density, so when the light particles encounter these rings, it is directed toward two focal points (near and distance; light changes direction and slows down when encountering an edge of discontinuity [principle of diffraction])<sup>53,55,58</sup> or three foci (near, intermediate, and distance) in case of the trifocal IOLs.<sup>53</sup>

Diffractive IOLs can be categorized as apodized and nonapodized. The term *apodization* is derived from the Greek words for “cutting off the feet.”<sup>58</sup> The apodized IOLs have a gradual decrease in diffractive step heights from the center to the periphery<sup>55,58</sup> to create a smooth transition of light between the focal points. Under myopic conditions (when the pupil is on mydriasis), the light is more focused to the distant point.<sup>55</sup>

These are the most commonly implanted multifocal IOLs.<sup>59</sup>

The steps on the nonapodized IOLs have a uniform height from the center to the periphery, so the light is equally distributed in both focal points independently of the pupil size.<sup>55</sup>

The extended range of vision IOLs is also diffractive, and they provide near vision by the correction of achromatic and spherical aberrations.<sup>60</sup>

**Refractive IOLs.** These IOLs have concentric zones of different dioptric power to achieve multifocality. They are pupil dependent and may be affected by decentration.

TABLE 3.10.3 Advantages and Disadvantages of Corneal Inlays

Advantages	Disadvantages
Minimally invasive	Patient must tolerate monovision
Reversible	Decrease in distance visual acuity
No need to remove corneal tissue	Decrease in contrast sensitivity
No need for a cataract	Presence of halos
Quick recovery	Corneal topography changes in the long term
Doesn't affect visual field testing	Induction of higher-order aberrations
Can be combined with other refractive procedures	Corneal haze in long term
Normal visualization of central and peripheral fundus	Inlay centration is crucial
	Dry eye

### Rotationally Asymmetrical IOLs (Varifocal)

These are characterized by an inferior segmental near add.<sup>57</sup> The IOL has a larger section for distance vision and a smaller reading segment, with only one transition zone. The near add varies from +1.5 D to +3.00 D, depending on the patient's visual needs.<sup>61</sup>

### Patient Selection Criteria

Adequate patient selection is the most important part in implanting a multifocal IOL. We must know the patient's visual expectations and make sure that we can fulfill them by selection of the correct IOL, because depending on the IOL design, the patient can have better near or intermediate distance vision. Also, patients' expectations have to be realistic, and we have to inform them of the visual side effects that they may experience with the multifocal IOLs (glare, halos) and that a process of neuroadaptation exists that takes a couple of months.

The correct IOL power calculation is crucial, and emmetropia should be the target. It has been reported<sup>62</sup> that the cause of 20% of cases of multifocal IOL explantation is incorrect IOL power.

Astigmatism correction is mandatory for a good performance of the multifocal IOL. Patients with irregular astigmatism are not good candidates for a multifocal IOL<sup>63</sup> because its correction is not easy or predictable.

Patients with corneal abnormalities like central scars and Fuchs' dystrophy are not suitable candidates for multifocal IOL implantation.<sup>63</sup>

Because many of the multifocal IOLs are pupil dependent, an adequate function before and after surgery is needed. Therefore, if a patient has a very small pupil diameter that needs surgical manipulation, the surgeon should be very careful to not damage the iris sphincter. Patients with larger pupils may experience glare and halos after multifocal IOL implantation.<sup>63</sup> Identification of zonular weakness during surgery is very important, as decentration or tilt of the multifocal IOL can have a detrimental effect on the visual acuity. This can be prevented by the implantation of a capsular tension ring.<sup>63,64</sup>

Any macular alteration must be recognized before implantation of a multifocal IOL, especially if the patient has these predisposing factors:

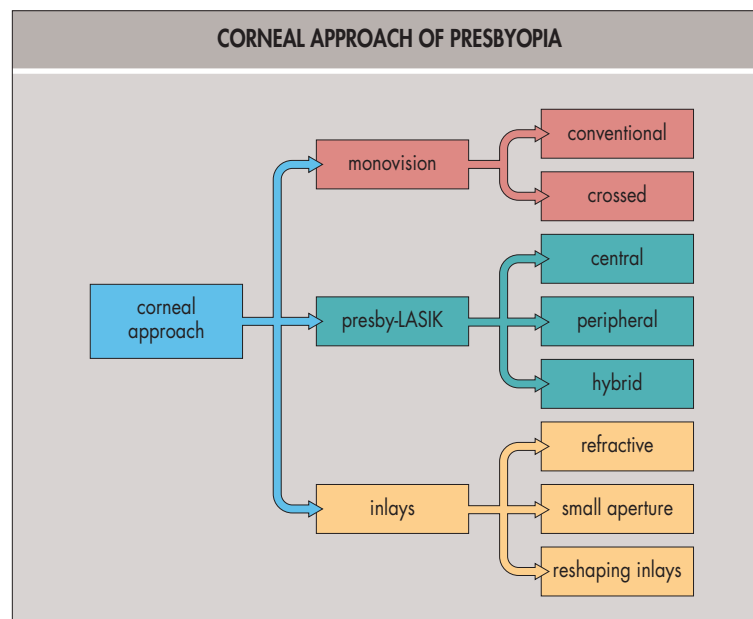

Fig. 3.10.7 Corneal Approach of Presbyopia.

TABLE 3.10.4 Corneal Inlays

Inlay	Material	Type of Inlay	Measurements	Mechanism of Action
Raindrop	Biocompatible hydrogel 80% water	Corneal reshaping inlay	Thickness of 10 $\mu$ m at the periphery and 32 $\mu$ m at the center Diameter: 2 mm	Reshapes the anterior corneal, creating a hyperprolate region $\rightarrow$ multifocal cornea
Flexivue	Clear copolymer of hydroxyethylmethacrylate and methylmethacrylate with an ultraviolet blocker	Refractive inlay	Thickness: 15–20 $\mu$ m Diameter: 3 mm	The central 1.8 mm diameter of the disc is plano in power (for distance vision), and the peripheral zone has an add power ranging from +1.25 D–3.0 D in 0.25 D increments (for near vision)
Icolens	Copolymer of hydroxyethyl methacrylate and methyl methacrylate	Refractive inlay	Thickness: 15 $\mu$ m Diameter: 3 mm	Bifocal design Central zone for distance and peripheral positive refractive zone for near
KAMRA	Polyvinylidene fluoride, nanoparticles of carbon	Small aperture inlay	Thickness: 5 $\mu$ m Diameter: 3.8 mm	Increases the depth of focus through the principle of small aperture optics

**Fig. 3.10.8 AcrySof Restor SN6AD3.** (Image from Alió J, Pikkel J. Multifocal intraocular lenses. The art and the practice. 1st ed. Editorial Springer; Switzerland 2014.)

male gender, former or current smoker, and history of heart disease.<sup>65</sup> A macular disease is a relative contraindication for the implantation of a multifocal IOL<sup>65</sup> because these patients have a reduced contrast sensibility that can be worsened by a multifocal IOL. Thus the macula should be evaluated with either a macular function test or OCT.

Retinal diseases like Stargardt and retinitis pigmentosa are absolute contraindications for multifocal IOL implantation. Other diseases like diabetic retinopathy, macular degeneration, and epiretinal membranes have a decreased contrast sensitivity that may be worsened by the multifocal IOL.<sup>63</sup> Glaucoma is a relative contraindication for the use of multifocal IOLs. If the patient has an early glaucoma or controlled ocular hypertension, a multifocal IOL can be implanted, but IOL implantation should be avoided in patients with progressive and advanced glaucoma.<sup>66</sup>

There are many multifocal IOLs available on the market; we will discuss the most popular ones.

**AcrySof Restor SN6AD3 (Alcon Laboratories, Inc.)**

Apodized diffractive and refractive technologies

Type: One-piece multifocal IOL

Material: hydrophobic acrylic

Filter: UV and blue light

Pupil dependent: No

Optic diameter: 6 mm

Overall diameter: 13 mm

Refractive index: 1.47

Power range: +6.00 to +34.00 D

Near addition at lens plane: +4.00 D

Incision size: >2.2 mm

The central 3.5 mm of the optic zone has 12 concentric steps of gradually decreasing (1.3–1.2) step heights. Surrounding this apodized region is the refractive area that directs light to a distance focal point for large pupil diameters.<sup>67</sup>

In bright light with constricted pupils, the lens sends light energy to near and distant focal points; in low light with dilated pupils, the apodized diffractive lens sends a greater amount of energy to distance vision to minimize visual disturbances (Fig. 3.10.8).<sup>68</sup>

**Lentis Mplus LS-313 (Oculentis GmbH)**

Type: one piece, refractive rotationally asymmetrical multifocal IOL (varifocal)

Material: HydroSmart acrylate copolymer with hydrophobic surface

Optic diameter: 6.0 mm

Overall diameter: 11.0 mm

Refractive index: 1.46

Addition at IOL plane: +3.00 D

Addition at spectacle plane: +2.5 D

**Fig. 3.10.9 Lentis Mplus LS-313 IOL.** (Image on the left from Alió J, Pikkel J. Multifocal intraocular lenses. The art and the practice. 1st ed. Editorial Springer; Switzerland 2014. Image on the right from <http://www.device.com.au/shop/oculentis/>.)

Diopter range: Mplus: +15.00 D to +25.00 D in 0.5 D steps, Mplus X: –10.00 D to +1.00 D in 1.0 D steps, and from +0.00 D to +36.00 D in 0.5 D steps

Incision size: 2.6 mm

360° continuous square optic and haptic edge (Fig. 3.10.9)

Pupil-independent IOL

The design has an inferior surface-embedded segment with the optical power required for near vision and seamless transitions between the near and far zones.

Light in the near vision zone is refracted to the near focus, and the rest is refracted to the far focus.<sup>59</sup>

Light hitting the transition area of the embedded sector is reflected away from the optical axis to prevent superposition of interference or diffraction.<sup>57,59</sup>

The position of the near segment does not have a detrimental effect on the visual performance,<sup>69</sup> although the manufacturer recommends an inferior placement.

**Symfony (Abbott Medical Optics, Inc.)**

Type: diffractive nonapodized achromatic

Material: UV-blocking hydrophobic acrylic

Optic diameter: 6 mm

Overall diameter: 13 mm

Power range: +5.00 D to +34.00 D in 0.50 D increments

Refractive index: 1.47

It has a biconvex wavefront-designed anterior aspherical surface and a posterior achromatic diffractive surface (Fig. 3.10.10).

This IOL elongates the focus and corrects the corneal chromatic and spherical aberration using an achromatic technology also known as “extended range of vision.”<sup>60,70</sup>

**Fig. 3.10.10 TECNIS Symphony IOL.** (Image from <http://eyewiretoday.com/news.asp?t=474>.)

**Fig. 3.10.11 AT LISA Tri 839 mp IOL.** (Image from Alió J, Pikkell J. Multifocal intraocular lenses. The art and the practice. 1st ed. Editorial Springer; Switzerland 2014.)

**Fig. 3.10.12 FineVision Micro F IOL.** (Image from Alió J, Pikkell J. Multifocal intraocular lenses. The art and the practice. 1st ed. Editorial Springer; Switzerland 2014.)

The chromatic aberrations have a detrimental effect on vision because they reduce contrast vision and induce blur.<sup>71</sup>

The improvement of both aberrations increases the retinal image quality with a better tolerance of decentration and without sacrificing the depth of field.<sup>72</sup>

It provides better near, intermediate, and distance vision than aspherical monofocal IOLs, and in contrast to multifocal IOLs, it does not induce aberrations to extend the depth of focus.<sup>60</sup>

Because it provides an elongated focal area rather than various focal points, halos are not as common as with the multifocal IOLs. In fact, one study<sup>70</sup> reported that 90% of patients in whom a Symphony IOL was implanted reported no or mild halos or photic phenomena, and the visual results were better than those obtained with a rotationally asymmetrical multifocal IOL or an apodized diffractive IOL.

#### **AT LISA tri 839 MP (Carl Zeiss Meditec AG)**

Type: one-piece trifocal diffractive aspherical IOL

Material: hydrophilic acrylic 25% with hydrophobic surface

Optic diameter: 6 mm

Overall diameter: 11 mm

Power range: from plano to +32.00 D in 0.5 D increments

Near addition at the IOL plane: +3.33 D for near vision, +1.66 D for intermediate vision

Incision size: 1.8 mm.

Asphericity:  $-0.18 \mu\text{m}$ .

The central 4.34 mm of the IOL optic is the trifocal zone, and the peripheral bifocal zone is from 4.34 to 6 mm with diffractive rings covering the entire optic diameter (Fig. 3.10.11).<sup>73</sup>

#### **Fine Vision Micro F (Physiol)**

Type: one-piece trifocal

Optic: diffractive anterior surface, aspherical posterior surface

Material: 25% hydrophilic acrylic

Optic diameter: 6.15 mm

Overall diameter: 10.75 mm

Power range: +10.00 D to +35.00 D in 0.5 D increments

Near addition at spectacle plane: +1.75 D intermediate vision, +3.5 D near vision

Incision size:  $>1.8 \text{ mm}$

Asphericity:  $-0.11 \mu\text{m}$

Pupil-dependent IOL

The anterior surface of the IOL is convoluted. By the varying of the height of the diffractive step, the amounts of light distributed to the near,

intermediate, and distant foci are adjusted according to the pupil aperture. The IOL distributes 43% of light energy to far vision, 28% to near vision, and 15% to intermediate vision for a 3-mm pupil, and the remaining light energy is lost (Fig. 3.10.12).<sup>74</sup>

#### **Panoptix (Alcon)**

Type: one piece, aspherical

Material: hydrophobic, ultraviolet- and blue light-filtering acrylate/methacrylate copolymer

Optic diameter: 6.0 mm

Overall diameter: 13.0 mm

It has a 4.5-mm diffractive area in the center with 15 diffractive zones and an outer refractive rim (Fig. 3.10.13).

Light distribution is 25% to near (40 cm), 25% to intermediate (60 cm), and 50% to distance vision.

There is a more physiological transition from different distances because of an advanced optical technology, so the light from the first focal point is diffracted to the distance focus. This helps to create a fourth focal point at 1.20 m, making this IOL a quadra-focal IOL, although it acts as a trifocal IOL.<sup>75</sup>

Based on laboratory simulations, the performances in image quality, photic phenomena, and resolution are equivalent between the Panoptix IOL and the AT LISA tri 839MP and FineVision Micro F trifocal IOL.<sup>76</sup>

#### **Clinical Outcomes and Quality of Life**

Carballo-Alvarez et al.<sup>74</sup> evaluated visual outcomes 3 months after bilateral implantation of the FineVision trifocal IOL. They reported adequate near, intermediate, and far vision, with satisfactory contrast sensitivity and no significant photic phenomena.

A comparison between the FineVision trifocal and the Restor IOL reported similar refractive outcomes, reading speeds, and patient

**Fig. 3.10.13 Panoptix IOL.** (Image from Kohnen T. First implantation of a diffractive quadrafoveal (trifocal) intraocular lens. *J Cataract Refract Surg* 2015;41:2330–2.)

satisfaction, although the intermediate distance in the defocus curve was better in the trifocal IOL group. Spectacle independence was achieved in 80% of the patients with the trifocal IOL and in 50% of the patients with the bifocal IOL.<sup>77</sup>

Similar outcomes were reported by a study comparing the Restor IOL with the AT LISA tri. The latter gave better intermediate visual acuity, whereas near and distance visual acuity were good with both IOLs. The Quality of Vision questionnaire showed similar visual disturbances between the two groups.<sup>78</sup>

A comparison of the visual outcomes and intraocular optical quality between the Lentis Mplus and the Restor IOL reported that the UNVA and distance-corrected near visual acuity (DCNVA) were better with the Lentis Mplus, although this IOL significantly induced HOA. The intermediate VA and the photopic contrast sensitivity were better with the Restor IOL.<sup>59</sup>

Patient satisfaction with multifocal and toric multifocal IOLs is very good, ranging from 93% to 95%.<sup>53</sup>

### Complications

The most common visual symptoms of multifocal IOLs are glare and halos.<sup>52,53,79</sup> These phenomena are secondary to the light division into two or more foci that happens with a multifocal IOL; the light in the out-of-focus image reduces the contrast of the in-focus image.<sup>52</sup>

Other symptoms include starbursts, shadows, and negative and positive dysphotopsia.<sup>53</sup> A decrease in contrast sensitivity has been reported also.<sup>52,53</sup> Multifocal aspherical IOLs have been developed to improve these visual phenomena. A meta-analysis compared the visual outcomes between aspherical and spherical multifocal IOLs, and aspherical multifocal IOLs achieved better image quality than spherical multifocal IOLs and also had less spherical aberrations.<sup>52</sup>

Although no multifocal IOL design exists without night vision disturbances, patients may adapt to them in a 6-month period<sup>53</sup> through a process of neuroadaptation,<sup>63</sup> which is faster with fully diffractive IOLs because the pupil does not affect the visual outcome.<sup>74</sup>

Posterior capsule opacification is the most common complication after cataract surgery. A study<sup>73</sup> compared the ND:YAG capsulotomy rates after the implantation of the FineVision Micro F and AT LISA tri 839MP trifocal IOLs, and the ND:YAG capsulotomy rate was significantly higher with the AT LISA tri 839MP IOL, although both IOLs had the same incidence of posterior cystoid macular edema.

It is important to note that not every patient is going to adapt to the multifocality and visual side effects, and some may want an IOL exchange (photopic phenomena and waxy vision can only be treated by IOL exchange). Kamiya et al.<sup>62</sup> reported the reasons for multifocal IOL explantation. The principal reason, accounting for 36% of all cases, was decreased contrast sensitivity; of these, 34% was for photopic phenomenon, 32% for unknown origin, including neuroadaptation failure, 20% for incorrect IOL power, 14% for preoperative excessive expectation, 4% IOL decentration, and 4% for anisometropia. It is important to note that 70% of the eyes from which the multifocal IOL was explanted had an UDVA of 20/20 or better, which means that the side effects of multifocal IOLs can be really disturbing for the patient (Table 3.10.5). See Table 3.10.6 for a review on Multifocal IOLs.

**TABLE 3.10.5 Multifocal Intraocular Lens Complications**

#### Complications Following Multifocal IOL Surgery

IOL decentration
IOL tilt
Inadequate pupil size
Residual refractive error
Posterior capsule opacification
Photopic phenomena and contrast sensitivity
Dry eye

### Accommodating IOLs

Accommodating IOLs have been designed to mimic physiological accommodation and avoid the optical side effects of multifocal IOLs.

IOLs proposed to restore accommodation have initially been designed to do so by enabling a forward movement of the optic component during an accommodation effort.<sup>80</sup>

These IOLs employ one of three basic approaches to restore accommodation:

1. Change in axial position
  - Single optic
    - The accommodative effect is dependent on IOL power,<sup>81</sup> so it provides limited near vision.<sup>82</sup>
      - Crystalens
      - Tetraflex
      - 1CU
  - Dual optic
    - They consist of a mobile front optic and a stationary rear optic that are interconnected with spring-type haptics.<sup>83</sup>
      - Synchrony
2. Change in shape or curvature
  - FluidVision
  - NuLens
3. Change in refractive index or power
  - Lumina

For the newest accommodating IOLs, researchers have found the sulcus instead of the capsular bag to be the ideal place to provide a real accommodative outcome. Capsular contraction has shown to be a major problem for accommodating IOLs implanted in the capsular bag. An asymmetrical capsular contraction causes the plate haptics to vault in opposite directions (Z-syndrome, Fig. 3.10.14),<sup>84</sup> inducing astigmatism, even >1 D of lenticular astigmatism.<sup>85</sup> Although this capsular contraction can be treated by an Nd:YAG laser capsulotomy, some patients may need an IOL exchange.<sup>85,86</sup>

Here we review some of the most popular and recently introduced accommodating IOLs:

#### 1) IOLs With Change in Axial Position, Single Optic

##### *Crystalens HD (Bauch & Lomb)*

This IOL was designed by Dr J. Stuart Cumming<sup>80</sup> and was the first accommodating IOL approved by the FDA.

Type: biconvex single-optic

Material: biocompatible third generation silicone (Biosil)

Refractive index: 1.428

Two sizes are available depending on the required power: 12.0 mm (HD520) for 10.00–16.50 D and 11.5 mm (HD500) for 17.00–33.00 D.

The center is biphase to increase the depth of focus, so it provides better near and intermediate focus.

It has a double mechanism to improve near visual: (1) axial movement of the optic and (2) variation of the radius of curvature of the anterior surface (Fig. 3.10.15).<sup>87</sup>

Alió<sup>87</sup> compared the visual acuity outcomes and ocular optical quality between the Crystalens HD and a monofocal IOL (Acri.Smart 48S). The UNVA was significantly better in the accommodating IOL group, but no significant difference in CNVA occurred between the two groups. Also there was no difference in the intraocular aberrometric coefficient.

A study comparing the visual outcomes between the Crystalens HD and the Lentis M-Plus<sup>88</sup> showed the latter achieved better DCNVA, and no significant differences occurred in postoperative UNVA or CNVA between the groups. The near add was reduced significantly after surgery in both groups, with a lower near-add power in the Lentis M-Plus group. Regarding optical quality, a significantly larger amount of IOL tilt existed in the Lentis M-Plus group, but the difference in mean ocular HOA was not statistically significant. The Crystalens HD had significantly better contrast

TABLE 3.10.6 Review of Multifocal IOLs

IOL Name*	Manufacturer	Near Addition (D)	Pupil Independent (Yes/No)	Aspheric (Yes/No)
Refractive (concentric rings)

\*Intraocular lens names are listed as spelled by the manufacturer and not per journal style.

**Fig. 3.10.14 Z-Syndrome Induced by Capsular Contraction.** (Image from Page TP, Whitman J. A stepwise approach for the management of capsular contraction syndrome in hinge-based accommodative intraocular lenses. Clin Ophthalmol 2016;10:1039–46.)

**Fig. 3.10.15 Crystalens IOL.** (Image from Alió JL, Plaza-Puche AB, Montalbán R, Javaloy J. Visual outcomes with a single-optic accommodating intraocular lens and a low-addition-power rotational asymmetric multifocal intraocular lens. J Cataract Refract Surg 2012;38:978–85.)

**Fig. 3.10.16 Tetraflex IOL.** (Image from Wolffsohn JS1, Davies LN, Gupta N, et al. Mechanism of action of the tetraflex accommodative intraocular lens. *J Refract Surg* 2010;26:858–62.)

sensitivity results under photopic conditions at all spatial frequencies. They concluded that both IOLs had limitations in providing complete near-vision outcomes.

With ray-tracing aberrometry, it was shown that the Crystalens accommodative power was lower than 0.4 D.<sup>89</sup>

Commercially available: Yes

#### 1CU (Human Optics AG)

Type: one-piece biconvex

Material: hydrophilic acrylic

Optic diameter: 5.5 mm

Total diameter: 9.8 mm

Mechanism of action: anterior movement of the optic; four haptics for the transduction of the ciliary muscle contraction

Saiki et al.<sup>90</sup> performed a 4-year follow-up of patients who received the 1CU IOL and reported that the amplitude of accommodation was not enough to provide good near vision. One possibility for the lack of accommodation is the contraction of the capsule.

Not commercially available; it has been discontinued

#### Tetraflex (Lenstec Inc)

Type: one-piece IOL

Material: hydroxyethylmethacrylate (HEMA)

Optic diameter: 5.75 mm

Overall diameter: 11.5 mm

Refractive index: 1.46

Incision size: 2.5–3.0 mm

Mechanism of action: Increase in HOA with accommodative effort<sup>91</sup> rather than forward movement within the capsular bag as was the original proposed action (Fig. 3.10.16).

Commercially available: Yes, although the results have been contradictory.

### 2) IOLs With Change in Axial Position, Dual Optic

#### Synchrony (Visiogen Inc.)

Type: one-piece dual optic

Material: silicone

Power range: +16.00 D to +28.00 D in 0.5 D steps

The anterior IOL component has a high plus power beyond that required to produce emmetropia, and the posterior component has a minus power to return the eye to emmetropia. A bridge with a spring function connects the two components. Once the IOL is in the capsular bag, the tension of the bag compresses the optics. This leads to strain energy in the haptics that is released when there is an attempt to accommodate (Fig. 3.10.17).<sup>82,92</sup>

A comparison of the visual and ocular performances between the Crystalens HD and the Synchrony IOL was made by Alió et al.<sup>82</sup> No statistically significant differences occurred in UDVA, CDVA, and near or intermediate visual outcomes between the two IOLs. Reading acuity and reading speed were similar in both groups. Contrast sensitivity was significantly better in patients who received the Synchrony IOL. HOA were higher in the Crystalens HD group. Both IOLs had limitations in providing adequate near visual outcomes.

**Fig. 3.10.17 Synchrony IOL.** (Image from Bohórquez V, Alarcon R. Long-term reading performance in patients with bilateral dual-optic accommodating intraocular lenses. *J Cataract Refract Surg* 2010;36:1880–6.)

Bohórquez et al.<sup>92</sup> evaluated reading ability at 1 and 2 years after the implantation of the Synchrony IOL. The reading speed, mean reading acuity, and mean critical print size were significantly better by 2 years postoperatively. They concluded that these results were a consequence of true accommodation, although the reasons for the improved reading skills at 2 years postoperatively were not fully clear.

Commercially available: No, it has been discontinued

### 3) IOLs With Change in Shape or Curvature

**FluidVision (Powervision, Inc).** This IOL has an overall diameter of 10.0 mm and an optic diameter of 6.0 mm. It is made of acrylic material; the haptics and interior of the optic are filled with silicone oil. During accommodation, the silicon oil is pushed into the optic through fluid channels that connect the haptics to the optic. This inflates the lens, which increases the dioptric power for near vision.<sup>93a</sup> When the eye focuses at far, fluid flows from the optic body back into the haptics, flattening the lens and decreasing the dioptric power.

In a pilot study, Roux reported a subjective accommodation of 2.5 D.<sup>93b</sup> The lens is implanted through a 4-mm incision; the results of this study have not been published yet.

Commercially available: No, still in trials.

**Nulens (DynaCurve).** This IOL consists of polymethyl methacrylate (PMMA) haptics, a PMMA anterior reference plane that provides distance vision correction, a small chamber that contains a solid silicone gel, and a posterior piston with an aperture in the center (Fig. 3.10.18).

Mechanism of action: The piston is pressed, making the flexible gel bulge and resulting in an increase or decrease in IOL optical power.

It is inserted at the sulcus and must be implanted through a limbal incision of 9 mm.

It can provide up to 10.00 D of accommodation, improving near visual acuity without compromising DVA.<sup>94</sup>

Commercially available: No

### 4) IOL With Change in Refractive Index or Power

**Lumina (Akkolens).** This IOL consists of two optical elements, each having an elastic U-shaped loop with a spring function, and nonelastic connections to the main body of the lens (Fig. 3.10.19).

The optics are aspherical. The anterior one has a power of 5.0 D, and the power of the posterior one depends on the required correction of the eye (10–25 D).

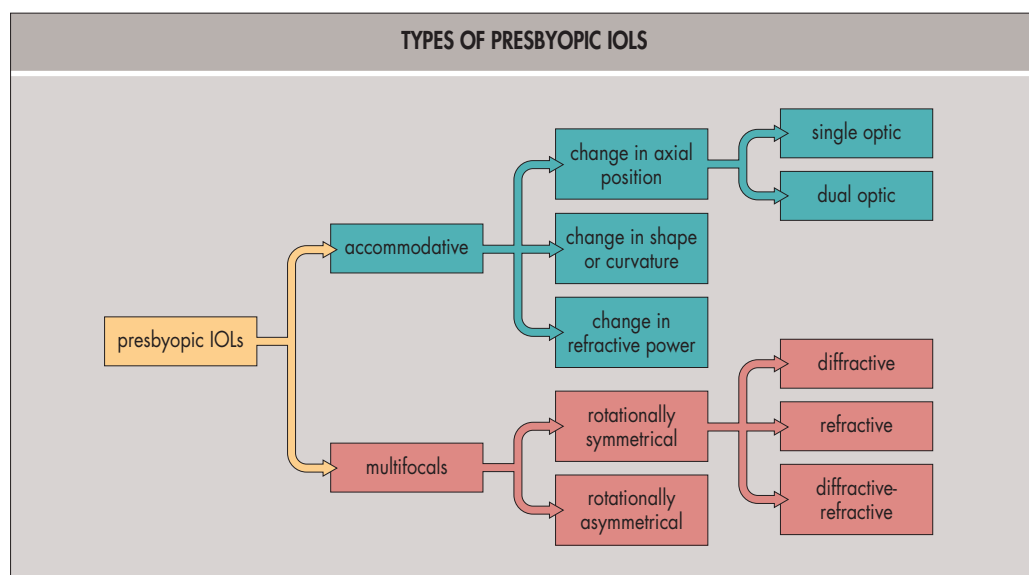

**Fig. 3.10.18 Nulens IOL in the Human Eye.** (Image from Alió JL, Ben-nun J, Rodríguez-Prats JL, et al. Visual and accommodative outcomes 1 year after implantation of an accommodating intraocular lens based on a new concept. *J Cataract Refract Surg* 2009;35:1671–8.)

**Fig. 3.10.19 Lumina IOL.** (Image from Alió JL, Simonov A, Plaza-Puche AB, et al. Visual outcomes and accommodative response of the Lumina accommodative intraocular lens. *Am J Ophthalmol* 2016;164:37–48.)

**Fig. 3.10.20 Types of Presbyopic IOLs.**

It must be implanted at the sulcus, and its size is customized based on the sulcus to sulcus diameter, as measured by OCT at the 12 o'clock meridian.

During accommodation, the IOL is compressed by the contraction of the ciliary muscle, and the optics move in opposite directions, increasing the optical power of the lens. When the muscle relaxes, the springs force the elements back to their original state, decreasing the optical power.

It has been proven through subjective and objective methods that the Lumina IOL improves near, intermediate, and far vision without affecting contrast sensitivity and with an accommodative power between 1.5 and 6.0 D.<sup>95</sup>

**Comments.** The long-term effectiveness of accommodating IOL implantation for presbyopia treatment still has to be demonstrated (Fig. 3.10.20).

### Other Treatments

#### Scleral Expansion Bands

This treatment is based on Schachar's theory of accommodation, which states that presbyopia is secondary to an increase in the lens diameter, which causes a reduction in the space between the lens and the ciliary body such that upon contraction the zonules can no longer exert their effect on the lens due to a loss of tension.<sup>96</sup>

The Refocus Group is conducting a phase III study of a new scleral implant surgery. Four PMMA segments are inserted in scleral tunnels at a depth of 400  $\mu$ m, 4 mm from the limbus to restore accommodation. Preliminary reports indicate good uncorrected near and intermediate

vision without compromise of distance vision. Primary outcomes are still pending.<sup>97</sup>

### Topical Treatment

This is an emerging topic that is under clinical evaluation; the mechanism of action is through ciliary body stimulation, miosis, and lens softening.

### FOV Tears

A topical treatment is available for the correction of near vision, with scientific evidence reporting a gain of two to three lines of UCVA. The ophthalmic solution contains pilocarpine, phenylephrine, polyethylene glycol, nepafenac, pheniramine, and naphazoline, and this combination stimulates the contraction of the ciliary body and maintains a physiological pupil diameter. FOV tears are commercially available in some Latin American countries.<sup>98</sup>

### Liquid Vision

This is a combination of aceclidine (parasympathomimetic) and tropicamide. Its mechanism of action is through a pinhole effect. The pilot study reported a gain of more than three lines of near vision. It is being tested in a phase IIb trial.<sup>99</sup>

### EV06 (Encore Vision)

An increment of the lens elasticity may be achieved by topical treatment with lipoic acid choline ester 1.5% (EV06, Encore Vision), which reduces the lens protein disulfides.

The lens disulfide bonds that form between the crystalline proteins are broken down because of the dihydrolipoic acid (a reduced active agent of lipoic acid), thus increasing the lens elasticity. A phase I/II study has shown good outcomes.<sup>100</sup>

# Corneal Anatomy, Physiology, and Wound Healing

## 4.1

Ayad A. Farjo, Matthew V. Brumm, H. Kaz Soong, Christopher T. Hood

**Definition:** The cornea represents the transparent anterior wall of the globe.

### Key Features

- The cornea, including the tear film, is the major refractive surface of the eye.
- It provides structural integrity for the anterior part of the eye.
- It is a key barrier against infection.

### INTRODUCTION

A healthy cornea, together with the overlying tear film, is necessary to provide a proper anterior refractive surface and to protect the eye against infection and structural damage to the deeper components of the eye. The average adult cornea is 11.5–12 mm<sup>1</sup> in horizontal diameter and about 1 mm smaller in vertical diameter. The anterior refractive power is +43.00 to +43.50 diopters (D). The shape of the cornea is prolate, being steeper centrally and flatter peripherally, which creates an aspherical optical system.

### Embryology, Anatomy, and Physiology of the Cornea

#### Epithelium

The corneal epithelium is derived from surface ectoderm at approximately 5–6 weeks of gestation. It is composed of nonkeratinized, nonsecretory, stratified squamous epithelium (Fig. 4.1.1), which is four- to six-cell-layers thick (40–50  $\mu\text{m}$ ). The epithelium is covered with a tear film of 7  $\mu\text{m}$  thickness, which is optically important in masking microirregularities of the anterior epithelial surface. The tear–air interface, together with the underlying cornea, provides roughly two thirds of the total refractive power of the eye. The mucinous portion of tears, which forms the undercoat of the tear film and is produced by the conjunctival goblet cells, interacts closely with the corneal epithelial cell glycocalyx to allow hydrophilic spreading of the tear film with each blink of the eyelid. The tear film also helps protect the corneal surface from microbial invasion and from chemical, toxic, or foreign body damage. Thus, the ocular surface tear film and the corneal epithelium share an intimate mutual relationship, both anatomically and physiologically.

Corneal epithelial cells undergo orderly involution, apoptosis, and desquamation. Complete turnover of corneal epithelial cells occurs in about 7–10 days,<sup>2</sup> with the deeper cells eventually replacing the desquamating superficial cells in an apically directed fashion. The most superficial cells of the corneal epithelium form an average of two to three layers of flat,

**Fig. 4.1.1** Cross-sectional view of the corneal epithelial cell layer.

polygonal cells. Extensive apical microvilli and microplicae characterize the cell membranes of the superficial cells, which, in turn, are covered by a fine, closely apposed, charged glycocalyx layer. The apical membrane projections increase the surface area of contact and adherence between the tear film's mucinous undercoat and the cell membrane. Laterally, adjacent superficial cells are joined by barrier tight-junctional complexes, which restrict entry of tears into the intercellular spaces. Thus a healthy epithelial surface repels dyes, such as fluorescein and rose bengal.

Beneath the superficial cell layer are the suprabasal or wing cells, so named for their cross-sectional alar shapes. This layer is about two to three cells deep and consists of cells that are less flat than the overlying superficial cells but possess similar tight, lateral, intercellular junctions. Beneath the wing cells are the basal cells, the deepest cellular layer of the corneal epithelium. The basal cell layer is composed of a single-cell layer of columnar epithelium approximately 20  $\mu\text{m}$  tall. Besides the stem cells and transient amplifying cells, basal cells are the only corneal epithelial cells capable of mitosis.<sup>3,4</sup> They are the source of both wing and superficial cells and possess lateral intercellular junctions characterized by gap junctions and zonulae adherens. The basal cells are attached to the underlying basement membrane by an extensive basal hemi-desmosomal system. This attachment is of pivotal importance in preventing the detachment of the multilayer epithelial sheet from the cornea. Abnormalities in this bonding system may result clinically in either recurrent corneal erosion syndromes or in persistent, nonhealing epithelial defects.

The basement membrane is composed of an extracellular matrix material secreted by the basal cells. Following destruction of the basement membrane, about 6 weeks are required for it to reconstitute and heal. The epithelial bond to the underlying, newly laid basement membrane tends to be unstable and weak during this period. The epithelium also adheres relatively poorly to bare stroma or Bowman's layer. Under ordinary conditions, type IV collagen and laminin are the major components of the basement membrane; however, fibronectin production increases to high levels during acute epithelial injury. The basement membrane, approximately 0.05  $\mu\text{m}$  in thickness, adheres to the underlying Bowman's membrane through a poorly understood mechanism that involves the anchoring fibrils and plaques.<sup>5</sup>

Epithelial stem cells—undifferentiated pluripotent cells that serve as an important source of new corneal epithelium—have been localized to the limbal basal epithelium. As the cells migrate to the central cornea, they differentiate into transient amplifying cells (cells capable of multiple but limited cellular division) and basal cells. The corneal epithelial cell layer mass appears to be the complex resultant of three phenomena. According to the “X, Y, Z hypothesis,” X is the proliferation of basal epithelial cells, Y is the centripetal mass movement of peripheral epithelial cells, and Z is the cell loss resulting from death and desquamation.<sup>6</sup> These three phenomena probably are not totally independent of each other but, rather, are controlled by a complex interactive feedback mechanism that maintains the status quo, vis-à-vis cell density, cell distribution and polarity, and cell layer thickness. These cytodynamics are likely to be responsible for the striking verticillate (vortex or whorl-like) biochemical deposition patterns seen in Fabry's disease (Fig. 4.1.2) and drug deposition keratopathies (e.g., from chloroquine and amiodarone). Langerhans' cells, immunologically

active dendritic macrophages derived from bone marrow and capable of antigen processing, are present in the peripheral corneal epithelium near the limbus. Under certain conditions (e.g., corneal graft rejection or injury), these cells are found among the central corneal epithelial cells. Human lymphocyte antigens are expressed by these corneal Langerhans' cells. Langerhans' cells have been detected in the epithelial basal cell layer and in Bowman's membrane in pathological inflammatory conditions, such as Thygeson's superficial punctate keratitis. After treatment with topical corticosteroids, these cells are no longer detectable by laser confocal microscopy.<sup>7</sup>

### Stroma

In week 7 of gestation, after the establishment of the primitive endothelium, a second wave of neural crest cells forms the early corneal stroma. Akin to the dermis of the skin, the corneal stroma provides important structural integrity and comprises roughly 90% of the corneal thickness. The stroma differs from other collagenous structures in its transparency and biomechanical properties. These functional properties result from the precise organization of stromal fibers and extracellular matrix, and the relatively dehydrated state of the corneal stroma.<sup>7-11</sup> The fibers are aligned in a parallel fashion within each lamella, and arranged at angles relative to fibers in adjacent lamellae.<sup>12,13</sup> This network reduces forward light scatter and contributes to the mechanical strength of the cornea. The peripheral stroma is thicker than the central stroma and the collagen fibrils may change direction to run circumferentially as they approach the limbus.<sup>13,14</sup> Bowman's membrane is the acellular condensate of the most anterior portion of the stroma.

The stromal collagen fibrils, which provide the major tensile strength to the cornea, are composed mostly of type I collagen, but require a heterodimeric complex with type V collagen to obtain their unique and narrow diameter.<sup>15-17</sup> They are surrounded by specialized proteoglycans, consisting of keratan sulfate or chondroitin sulfate/dermatan sulfate side chains, which help regulate hydration and structural properties. Keratocytes, the major cell type of the stroma, comprise approximately 10% of the stroma by volume and are involved in maintaining the extracellular matrix environment.<sup>18,19</sup> More keratocytes are situated in the anterior stroma than in the posterior stroma.<sup>20</sup> Morphological differences between the anterior and posterior stromal keratocytes, such as fenestrations, have been identified.<sup>21</sup> Corneal “crystallins,” representing 25%–30% of soluble protein in keratocytes, appear to be responsible for reducing backscatter of light from the keratocytes and maintaining corneal transparency.<sup>22</sup>

Dua et al. have proposed unique biomechanical properties of the most posterior 6–15 microns of the stroma (pre-Descemet's layer [PDL]<sup>23,24</sup>). These five to eight lamellae of compact collagen appear distinct on electron microscopy and may be of relevance as a plane of cleavage in keratoplasty. The electron microscopic details of this membrane were first illustrated in 1972 by Fine and Yanoff.<sup>25</sup>

Corneal shape and curvature are governed by the intrinsic biomechanical structure and extrinsic environment (Fig. 4.1.3). Anterior corneal stromal rigidity in particular appears to be important in maintaining the corneal curvature.<sup>26</sup> Organizational differences in the collagen bundles of the anterior stroma may contribute to a tighter cohesive strength in this

**Fig. 4.1.2** Whorl-like deposition keratopathy in corneal epithelium seen in Fabry's disease.

**Fig. 4.1.3** Major corneal loading forces in the steady state. (Illustration courtesy William J. Dupps, MD, PhD.)

area and may explain why the anterior curvature resists change to stromal hydration much more compared with the posterior stroma, which tends to develop folds more easily. Corneal nerves and sensation are derived from the nasociliary branch of the first (ophthalmic) division of the trigeminal nerve. In the superficial cornea, the nerves enter the stroma radially in thick trunks forming plexiform arrangements, which eventually perforate Bowman's membrane to provide a rich plexus beneath the basal epithelial layer.<sup>27</sup> The fibers appear to directly communicate with keratocytes and epithelial cells<sup>28</sup> and may play an important role in corneal homeostasis.

### Endothelium

In early embryogenesis, the posterior cornea is lined with a neural crest-derived<sup>29</sup> monolayer of orderly arranged cuboidal cells.<sup>30</sup> By the 78-mm stage, the cells become flattened and tightly abut one another. At this stage, immediately anterior to the flattened layer is a discontinuous, homogeneous acellular layer, which in time becomes Descemet's membrane.<sup>31</sup> By the 120-mm and 165-mm stages of development, the endothelial monolayer is uniform in thickness, spans the entire posterior corneal surface, and fuses with the cells of the trabecular meshwork.<sup>31</sup> Similarly, Descemet's membrane becomes continuous and uniform, fusing peripherally with the trabecular beams.<sup>31</sup> The fusion site, known as Schwalbe's line, is a gonioscopic landmark that defines the end of Descemet's membrane and the start of the trabecular meshwork. At birth, the endothelium is approximately 10  $\mu\text{m}$  thick.<sup>32</sup>

The intact human endothelium is a monolayer, which appears as a honeycomb-like mosaic when viewed "en face" (Fig. 4.1.4). The individual cells continue to flatten over time and stabilize at about 4  $\mu\text{m}$  in thickness in adulthood (Fig. 4.1.5).<sup>33</sup> The posterior surface of the endothelium is devoid of villi, except in certain pathological conditions, in which it may develop epithelioid characteristics. Adjacent cells share extensive lateral interdigitations and possess gap and tight junctions along their lateral borders. The lateral membranes contain a high density of sodium ( $\text{Na}^+$ ), potassium ( $\text{K}^+$ )-adenosine triphosphatase (ATPase) pump sites.<sup>34</sup> The basal surface of the endothelium contains numerous hemi-desmosomes that promote adhesion to Descemet's membrane. Endothelial cells contain numerous mitochondria and a prominent Golgi apparatus, and continuously secrete

**Fig. 4.1.4 Specular Photomicrograph of Normal Endothelium.** Note the dark, well-defined cell borders, the regular hexagonal array, and the uniform cell size. (Bar = 50  $\mu\text{m}$ .)

**Fig. 4.1.5 Light Micrograph of Normal Endothelium ( $\times 100$ ).** Note the single-cell endothelial layer with a Descemet's membrane of uniform thickness (epithelial surface at top of figure). (Courtesy Dr David Barsky.)

Descemet's membrane throughout life, beginning in utero at the week 8 stage. The anterior portion of Descemet's membrane formed in utero has a distinctive banded appearance when viewed by electron microscopy, but Descemet's membrane produced after birth is unbanded and has an amorphous ultrastructural texture. This membrane is approximately 3  $\mu\text{m}$  thick at birth, but thickens to 10  $\mu\text{m}$  with age. Endothelial cell density and topography continue to change throughout life. From the second to eighth decades of life, the cell density declines from approximately 3000–4000 cells/ $\text{mm}^2$  to around 2600 cells/ $\text{mm}^2$ , and the percentage of hexagonal cells declines from about 75% to around 60%.<sup>35</sup> The central endothelial cell density decreases at an average rate of 0.3% per year in normal corneas.<sup>36</sup>

As a result of endothelial activity, the stroma is maintained in a relatively deturgesced state (78% water content).<sup>37</sup> One hypothesis is that this endothelial activity is mediated by a pump-leak process; net fluid egress from the corneal stroma follows movement down an osmotic gradient from a relatively hypo-osmotic stroma toward a relatively hypertonic aqueous humor. This passive bulk fluid movement requires no energy. The energy-requiring processes are the intracellular and membrane-bound ion transport systems, which generate the osmotic gradient. The two most important ion transport systems are the membrane-bound  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase sites and the intracellular carbonic anhydrase pathway.<sup>38</sup> Activity in both these pathways produces a net flux from stroma to aqueous humor. The barrier portion of the endothelium is unique in that it is permeable to some degree, permitting the ion flux necessary to establish the osmotic gradient.<sup>31,33</sup>

Little in vivo mitotic potential exists within the normal endothelium but may come into play in pathological situations. Although the exact minimum number of cells per millimeter squared required to maintain corneal deturgescence is not known, corneas with central cell counts below 500 cells/ $\text{mm}^2$  may be at risk for development of corneal edema. Endothelial cell morphology (size and shape) appears to correlate with pump function. An increase in cell size (polymegathism) and an increase in variation of cell shape (pleomorphism) correlate to reduced ability of the endothelial cells to deturgesce the cornea.<sup>39,40</sup>

In vivo assessment of endothelial function relies on measurements of corneal thickness or on clinical morphological studies of the endothelial monolayer with specular microscopy. Measurement of the corneal thickness (pachymetry) indirectly reflects endothelial function. The average central corneal thickness is around 0.5 mm and gradually increases toward the periphery to around 0.7 mm. Normally, as a diurnal variation, corneas tend to be slightly thicker just after the person awakes in the morning. This increase in thickness is the consequence of diminished evaporation of water from underneath the closed eyelids, and the result of reduced nocturnal metabolic activity of the endothelium. Such overnight corneal swelling is more exaggerated in persons with unhealthy endothelium, causing blurred vision in the morning, but it gradually resolves later during the day.

### Endothelial Responses to Stress

Mild endothelial stress may result in cell size and shape changes, whereas greater stress may result in cell loss as well as irreversible alterations in the endothelial cytoskeleton.<sup>41</sup> Sources of stress may include metabolic disorders (hypoxia or hyperglycemia), toxins (drugs or their preservatives), injury (trauma or surgery), or alterations in pH or osmolarity. For example, contact lenses cause a hypoxic stress of varying degree to the endothelium.<sup>42</sup> Over time, this may result in alteration of the morphology, microanatomy, and possibly the function of the endothelium.<sup>43,44</sup> Hyperglycemia is another common metabolic stress that may produce changes in the endothelium. When compared with age-matched controls, the corneal endothelium in patients with type 1 and type 2 diabetes has a lower mean cell density and greater pleomorphism and polymegathism.<sup>45,46</sup>

Tissue manipulation, fluid flow in the anterior chamber, and intracameral pharmacological agents introduced during anterior segment surgery may cause damage to the endothelium.<sup>47,48</sup> Ophthalmic viscoelastic materials (composed of hydroxypropyl methylcellulose, chondroitin sulfate, or sodium hyaluronate) provide significant protection against intraoperative trauma to the endothelium.<sup>49,50</sup>

Glaucoma has been associated with endothelial cell loss. Compared with age-matched controls, significantly lower endothelial cell counts were noted in patients with glaucoma and ocular hypertension in one study.<sup>51</sup> Cell counts were inversely proportional to the mean intraocular pressure in the glaucoma and ocular hypertension groups. Mechanisms of cell loss may include direct damage from intraocular pressure, congenital alterations of endothelium in glaucoma, and drug toxicity.<sup>52</sup>

**Fig. 4.1.6** Light Micrograph That Shows the Leading Edge of Migrating Rat Corneal Epithelium as It Tapers to a Layer of One-Cell Thickness. As the epithelial defect is rapidly covered by migrating cells, it is initially coated with a thin, rarefied cell population prior to onset of mitotic activity (hematoxylin & eosin).

## CORNEAL WOUND HEALING

### Epithelial Injury

Within minutes after a small corneal epithelial wound, cells at the edge of the abrasion begin to cover the defect as rapidly as possible by a combination of cell migration and cell spreading. A longer delay of up to 4–5 hours is seen in larger defects. This lag phase is necessary for the preparatory cellular changes of an anatomical, physiological, and biochemical nature to occur before rapid cell movement. Various cell membrane extensions, such as lamellipodia, filopodia, and ruffles, develop at the leading edge of the wound. Anchoring hemi-desmosomes disappear from the basal cells. This early nonmitotic wound coverage phase is remarkable for its speed; the cells have been measured to migrate at a rate of 60–80  $\mu\text{m}/\text{h}$  (Fig. 4.1.6).<sup>53</sup> The migrating sheet of epithelial cells is attached most firmly to the underlying substrate at the leading margin. The relatively firmer adhesion at the leading margin suggests that the epithelial sheet movement may have “front-wheel drive,” with the less well-anchored cells behind the leading margin being pulled forward, possibly by intracellular contractile mechanisms that involve actin.<sup>54</sup> Fibronectin, a ubiquitous extracellular matrix protein present in plasma and in fresh wounds, is thought to be one of the key elements in the mediation of cell-to-substrate adhesion and cell migration. Present on the extracellular side of adhesion plaques, it is thought to mediate the linkage between the vinculin–talin–integrin complex and the substrate during epithelial migration after a wound has occurred. Laminin, a less ubiquitous extracellular matrix protein, is thought to serve a similar function.

At 24–30 hours after medium-sized epithelial injuries, mitosis or cell proliferation begins and restores the rarefied epithelial cell population. After large epithelial injuries, significant increases in cellular division occur as late as 96 hours.<sup>55</sup> Only the basal cells, transient amplifying cells, and the limbal stem cells partake in this reconstitutive mitosis.<sup>3,4</sup> The corneal epithelial stem cells, which reside at the limbus in the Pallisades of Vogt, cannot be regenerated after injury.<sup>56,57</sup> Limbal stem cell deficiency is an increasingly recognized cause of nonhealing epithelial defects. The extracellular matrix, in addition to other environmental signals, such as cytokines and growth factors, likely plays a central role in regulating epithelial stem cell commitment, corneal differentiation, and participation in corneal wound healing.<sup>58</sup> In laboratory and clinical trials, agents known to influence epithelial migration, mitosis, apoptosis, adhesion, and differentiation have been studied as possible therapeutic agents to enhance corneal epithelial healing, including growth factors, fibronectin, and retinoids. Primarily mitogenic agents and growth factors also stimulate production of extracellular matrix components to enhance cell-to-substrate adhesion. Bowman’s layer does not regenerate following injury.

Various pathological conditions may delay or prevent the normal corneal epithelial healing process. These include the following: damage to the cellular substrate (caused by herpetic or other infectious disease, diabetes mellitus, chemical burns, or basement membrane injuries and/

**Fig. 4.1.7** Recurrent Erosion in a Diabetic Cornea. Note the abnormally thick basement membrane (asterisk) and the intralamellar split within (arrow) (hematoxylin & eosin).

or dystrophies), ocular surface inflammation or atopic disease, medication, dry eyes, neurotrophic and exposure keratopathies, conjunctival disease (e.g., mucous membrane pemphigoid, radiation keratoconjunctivitis, and Stevens–Johnson syndrome), extensive damage to the limbal stem cells, and eyelid abnormalities.

In neurotrophic corneas, it is possible that interruption of corneal innervation results in depletion of growth factors and substance P, a neurogenic chemical known to regulate corneal physiological functions.<sup>59</sup> Diabetic corneas may manifest as abnormally thickened and easily delaminated basement membranes (Fig. 4.1.7), perhaps akin to basement membrane abnormalities elsewhere, as in the ciliary epithelium and the renal glomeruli.<sup>52</sup> A combination of pharmacological interruption of corneal nerve function and damage to the epithelial cells and substrate may cause persistent epithelial defects associated with topical anesthetic abuse.<sup>60,61</sup> Evidence also implicates matrix metalloproteinase-9 (gelatinase B) as a factor that may impact epithelial healing and/or desquamation.<sup>62,63</sup>

### Stromal Injury

Similar to skin, stromal wound healing consists of repair, regeneration, and remodeling,<sup>15</sup> involving a complex interplay of cytokines, growth factors, and chemokines.<sup>64</sup> Importantly, stromal repair differs from dermatological healing in that it occurs avascularly and ideally maintains corneal clarity. The reparative cascade begins with activation of stromal keratocytes (Fig. 4.1.8), which enlarge in size within the first 6 hours after injury and migrate into the injured area within 24 hours, becoming more fibroblast-like in appearance and behavior.<sup>65</sup> Activation of the keratocytes may be triggered by epithelial factors,<sup>65</sup> and regeneration of a fully functional epithelial basement membrane appears to have a critical role in the maintenance of corneal stromal transparency after mild injuries and recovery of transparency when opacity is generated after severe injuries.<sup>67</sup> The reparative cascade that follows typically results in corneal opacity in the affected area. The keratocytes within the area of injury undergo apoptosis, peaking 4 hours after the initial insult.<sup>66</sup> Apoptosis appears to modulate the wound healing response by influencing the activation of adjacent keratocytes.

Within 1–2 weeks, myofibroblasts with contractile properties enter the area under the epithelium and become involved in the remodeling of the stroma, with increased expression of matrix metalloproteinases.<sup>15,68</sup> These cells may be responsible for the “haze” seen after corneal injury or surgery.<sup>70</sup> The remodeling process sometimes can continue over a prolonged period of several years and may eventually restore corneal clarity in the affected area. Certain corneal surgeries, such as laser in situ keratomileusis, may cause a progressive loss of keratocytes over time through an as yet unclear mechanism.<sup>69</sup>

### Endothelial Injury

Nonpenetrating puncture injuries of the anterior cornea that do not directly involve the endothelium (e.g., those that occur when the cornea is struck by small, high-velocity particles) may cause concentric lesions of

**Fig. 4.1.8** Transmission electron micrograph of the corneal stroma. Activated keratocytes with dilated endoplasmic reticulum (*inset: black arrow*) and prominent nucleoli (*white arrow*) 1 week after keratoplasty. Bowman's layer is at the upper border of the micrograph. A normal keratocyte (*asterisk*), noticeably smaller than the activated cells, is visible above the scale bar. (Bar = 5.0  $\mu\text{m}$ .) (Reproduced with permission from Ohno K, Mitooka K, Nelson LR, et al. Keratocyte activation and apoptosis in transplanted human corneas in a xenograft model. *Invest Ophthalmol Vis Sci* 2002;43:1025–31.)

the endothelium arising from rapid focal distortion of the cell layer. Buckling of the endothelial layer also can result from excessive corneal bending in large-incision surgeries and/or from lens fragments striking the endothelium during cataract surgery and may occasionally produce snail-track lesions, clinically seen as serpentine, grayish lines on the endothelium. The damaged cells are rapidly replaced by enlargement of the surrounding cells and their centripetal migration into the injured region. Clinically, by slit-lamp biomicroscopy, these endothelial lesions disappear 1–3 days after injury. With more severe trauma, the underlying Descemet's membrane

may even be torn or ruptured, as in forceps delivery injuries and in corneal hydrops in keratoconus. When injured, Descemet's membrane curls in toward the stroma and surrounding endothelial cells slide in to cover the defect and produce new Descemet's membrane.<sup>72</sup> Although normal endothelium does not appear to replicate in vivo, recent evidence suggests that endothelial cells retain a degree of latent proliferative potential even into adulthood.<sup>71</sup> Recently, rho-kinase inhibitors have demonstrated potential in treating endothelial damage, with evidence of accelerated endothelial cell spread in rabbit models and clearing of corneal edema in small human trials.<sup>73</sup>

Anterior Segment Imaging Modalities

Anam Akhlaq, Paula Kataguir, Ricardo Nosé, Nicolas J. Pondelis, Pedram Hamrah

4.2

**Definition:** Anterior segment (AS) imaging allows topographic, anatomical, and cellular visualization of ocular tissues.

Key Features

- Anterior segment optical coherence tomography is essential in pre- and postoperative evaluation for lamellar corneal transplantations, refractive surgery, and ectasia-related disorders. It may be utilized for the diagnosis and management of ocular surface neoplasia.
- Ultrasound biomicroscopy is a valuable tool for the assessment of anterior segment tumors and corneal opacities.
- Specular microscopy is useful in evaluation of the corneal endothelium, in Fuchs’ endothelial corneal dystrophy and for preoperative planning of anterior segment surgery.
- In vivo confocal microscopy has a high sensitivity and specificity for detection of *Acanthamoeba* and fungal keratitis. It can be utilized in the evaluation of corneal nerve and inflammatory changes in the cornea for dry eye disease, neuropathic corneal pain, neurotrophic keratopathy, and related conditions. It also has utility in visualization of *Demodex* mites in the eyelids.
- Topography and wavefront imaging are critical in the evaluation and management of refractive surgery, cataract surgery, corneal transplantations, astigmatism, and corneal ectasia.
- Meibography can be used to assess structural abnormalities of meibomian glands in dry eye disease and related disorders.

INTRODUCTION

Advances in anterior segment (AS) imaging over the past decade have revolutionized clinical care by allowing topographical, anatomical, and cellular visualization of tissues. The choice of imaging modalities used depends on the tissue to be visualized and the suspected pathology. AS optical

coherence tomography (AS-OCT), for example, can be used to visualize anatomical structures anterior to the iris, and the structures behind the iris are best seen with ultrasound biomicroscopy (UBM). In vivo confocal microscopy (IVCM) provides layer-by-layer images of the entire cornea at a cellular level, whereas specular microscopy can best assess the corneal endothelium. Corneal topography and wavefront imaging can visualize topography-related abnormalities. Finally, meibography demonstrates meibomian gland (MG) abnormalities that are difficult to discern with slit-lamp biomicroscopy. The detailed principles, functions, and clinical applications of AS imaging modalities are discussed below.

ANTERIOR SEGMENT OPTICAL COHERENCE TOMOGRAPHY

AS-OCT is a noninvasive, noncontact imaging device that allows cross-sectional, anatomical imaging of the eye,<sup>1</sup> with the use of an interference pattern of reflected light,<sup>2-4</sup> and relies on images reconstructed from cross-sectional scans (A-scans). Since the advent of original time domain (TD) OCT, the technology has rapidly evolved with the development of the higher resolution Fourier domain (FD-OCT) (5-μm FD-OCT versus 18-μm TD-OCT resolution), and faster speed of A-scans (26,000 scans/sec FD-OCT versus 2,000 scans/sec TD-OCT), resulting in fewer motion artifacts and the capability to obtain three-dimensional images of ocular tissues. The more recent spectral domain (SD, 5 μm) and swept-source (SS, up to 2.6 μm) OCTs provide even higher-resolution images (SD, 5 μm and SS, up to 2.6 μm) and higher speed of A-scans (about 50,000 scans/sec SD-OCT versus 100,000 scans/sec SS-OCT).<sup>3</sup> Although TD AS-OCT has deeper penetration due to longer wavelength, the SD-OCT and SS-OCT have better signal-to-noise ratio and allow for more structural detail.<sup>5</sup> A comparison summary of the types of AS-OCT devices is provided in Table 4.2.1.

Application of the “en face” technique provides a layer-by-layer horizontal sectioning of the tissue. These sections allow for identification of microstructural information throughout the scanned area that is not available with standard AS-OCT scans. Moreover, AS-OCT angiography (OCTA), which has recently been described, allows for visualization and quantification of vessel density in the cornea, iris, and sclera (Fig. 4.2.1).<sup>6</sup>

**Fig. 4.2.2** Anterior segment optical coherence tomography (AS-OCT) showing tear film height, depth, and area.

## Clinical Applications

### Tear Film Evaluation

Tear meniscus height, depth, area, radius of curvature, and volume can be measured using AS-OCT (Fig. 4.2.2).<sup>1</sup> Thus, AS-OCT is a valuable noninvasive tool for the evaluation of the tear film abnormalities.

### Refractive Surgery and Ectasia-Related Disorders

AS-OCT scans of the healthy corneas show corneal layers as seen in Fig. 4.2.3, A, and allow for the evaluation of flap thickness and stromal bed after refractive surgery.<sup>1</sup> Thus AS-OCT measurements of preoperative corneal thickness and postoperative residual stroma thickness may help in risk stratification of patients by an ectasia scoring system.<sup>17</sup> Similarly, corneal thinning can be measured by using AS-OCT for screening,

risk-assessment, and diagnosis of patients with ectasia-related disorders by assessment of area and range of thinning (see Fig. 4.2.3B).<sup>1,8</sup> Postoperative AS-OCT can further be used to monitor complications, such as interface fluid or haze, and flap dislocation.<sup>1</sup> Patients with prior refractive correction, who require cataract surgery may benefit from additional data obtained using AS-OCT for the latest biometry formulas to improve surgical outcomes.<sup>1</sup>

### Penetrating and Endothelial Keratoplasty-Related Procedures

AS-OCT can provide valuable information both intraoperatively and postoperatively for penetrating corneal grafts and endothelial keratoplasty detachment. Endothelial grafts can be visualized on AS-OCT for

**Fig. 4.2.3** An anterior segment optical coherence tomography (AS-OCT) image of (A) normal cornea; (B) keratoconus, seen as central corneal thinning, identified with markings; (C) endothelial corneal graft, shown with yellow arrow; and (D) corneal keratoprosthesis; arrows show posterior side of the front plate of the keratoprosthesis.

orientation, position and interface fluid intraoperatively, and for detachment postoperatively using warning signs, such as interface fluid and poor margins.<sup>9,10</sup> Intraoperative AS-OCT can assess dissection depth in deep anterior lamellar keratoplasty (DALK) and identify graft orientation and the need for repositioning for Descemet's membrane endothelial keratoplasty (DMEK) and Descemet's membrane stripping automated endothelial keratoplasty (DSAEK).<sup>10</sup> Postoperative graft adherence/detachment status in DMEK and DSAEK also may be seen (Fig. 4.2.3C).<sup>1,9</sup> Moreover, keratoprosthesis (KPro) offers a useful alternative for patients with severe corneal pathology, (Fig. 4.2.3D), identifying corneal thinning and melting under the front plate.<sup>9</sup>

### Ocular Surface Tumors

Although conjunctival and corneal tumors can be observed clinically by using slit-lamp biomicroscopy, their exact location, depth, extent, and

**Fig. 4.2.4** Anterior segment optical coherence tomography (AS-OCT) showing (A) conjunctival tumor extending to the corneal epithelium; the lesion is seen as hyperreflective epithelium; (B) conjunctival nevus; lesion shows cystic spaces on AS-OCT.

anatomic relationship to surrounding structures can be assessed further by using AS-OCT (Fig. 4.2.4).<sup>8,11</sup> AS-OCT can complement UBM in imaging and is superior to UBM for imaging ocular surface tumors.<sup>11,12</sup> For example, squamous cell neoplasia presents as a localized area of hyperreflective thickened epithelium with an abrupt transition between the normal and thickened area; a lymphoma manifests as a hyporefective, homogeneous subepithelial mass; a melanoma presents as a hyperreflective subepithelial mass; and nevi present with cysts in a subepithelial mass.<sup>11,12</sup>

### Cataract Surgery and Intraocular Lens Implantation

Pre- and postoperative AS-OCT imaging helps assess the anterior chamber (AC) in evaluation of phakic intraocular lenses.<sup>1</sup> Preoperative AS-OCT can determine the AC angle, width, and lens rise, whereas postoperative AS-OCT can evaluate surgical wounds and assess for complications, including angle-closure glaucoma and corneal decompensation.<sup>1</sup> Further, as detailed above, AS-OCT may aid in biometry in patients who have previously undergone LASIK surgery.

TABLE 4.2.2 Types of Commercially Available Specular Microscopes

	CEM-530 (Nidek Fremont, CA)
	EM-3000 (Tomey, Inc., Phoenix, AZ)
	SP-1P (TopCon Medical, Inc., Tokyo, Japan)

Keratitis

Keratitis may be diagnosed clinically, but the areas of necrosis and infiltration may be better assessed by using AS-OCT, particularly in opaque corneas. Because AS-OCT allows for quantitative measurement of corneal thickness, it serves as an additional aide in detection and treatment of keratitis and corneal ulcers.<sup>1</sup> Localization of stromal necrosis and radial hyperreflective stromal bands in *Acanthamoeba* keratitis can further be translated for rapid diagnosis and reduction of perforation rates as a result of earlier intervention.<sup>1,13</sup>

Miscellaneous Uses

AS-OCT has several other applications, such as grading of cells in anterior uveitis and visualization of intracorneal implants.<sup>1</sup> Further, it is useful in screening corneas from eye banks for corneal abnormalities, such as prior LASIK surgery.

Limitations

AS-OCT has limited ability to visualize structures posterior to iris as a result of pigmentation, whereas UBM is more useful clinically.

SPECULAR MICROSCOPY

Specular microscopy allows for imaging and analysis of the corneal endothelium. It works on the basic principle of light reflection using a mirror: the angle of incidence is equal to that of reflection. As light passes through a media with higher index of refraction, most of it is reflected; this reflected light is captured by a detection lens. The endothelial cells can be imaged because their refractive index is greater than that of the aqueous humor. The light source can be a stationary or moving slit or spot; wider slit allows greater field, but reduced contrast and resolution.<sup>14</sup> Specular microscopy can be contact or noncontact and automated or manual, or both.<sup>15</sup> The types of specular microscopes are shown in Table 4.2.2.

Specular microscopy provides pachymetric measurements and endothelial cell analysis (density and morphology), including endothelial cell density, mean cell area, coefficient of variation (standard deviation divided by mean area of cells), and percentage of hexagonality or pleomorphism (percentage of cells with variation from normal hexagonal shape). Coefficient of variation and pleomorphism are the more sensitive indicators of endothelial dysfunction and stress, as even at low endothelial density (<500 cells/mm<sup>2</sup>) the endothelial function may remain uncompromised.<sup>15</sup>

The fixed-frame method allows for cell quantification within a fixed area (Fig. 4.2.5A), and the variable-frame method allows the observer to make an accurate boundary around the edges of the cells.<sup>15,16</sup> In contrast, the center method requires the centers of contiguous cells to be marked manually, hence peripheral cells are not counted as they do not have adjoining cells. Moreover, the center-flex method requires delineating the boundary of an area, followed by marking of cell centers.

Clinical Applications

The normal corneal endothelium comprises hexagonal and similar size cells (see Fig. 4.2.5A).<sup>17</sup> The cell density decreases with aging (0.5% per year). Examples of cell abnormalities include guttae (excrecences of the Descemet’s membrane).<sup>16</sup> Contact lens wear can cause transient or chronic changes to the endothelial cell morphology.<sup>16</sup>

Corneal Dystrophies

Specular microscopy is a valuable tool to diagnose different endothelial disorders, such as Fuchs’ endothelial corneal dystrophy (FECD), posterior polymorphous dystrophy (PPMD), or iridocorneal endothelial (ICE)

Fig. 4.2.5 Specular microscopy image of (A) normal endothelium quantified using fixed-frame method; (B) endothelium with Fuchs’ endothelial corneal dystrophy; note the presence of guttae (arrow) and dysmorphic cells.

syndrome.<sup>18,19</sup> In FECD, the mosaic endothelium presents dark areas (guttae) (see Fig. 4.2.5B).<sup>20</sup> Bilateral involvement, with donut-shaped vesicles and clearly defined black rings anterior to the cells may be seen in PPMD; whereas in ICE syndrome, many pentagonal cells are seen with intracellular dark areas.<sup>19</sup> In advanced ICE disease, a “reversal appearance” occurs with black areas and white margins.

Intraocular Surgery Evaluation

Permanent corneal edema occurs at low epithelial cell density (300–700 cells/mm<sup>2</sup>) or presence of other morphological abnormalities (coefficient of variation >40% or <50% hexagonal cells). Loss of cells with ocular surgery is estimated to be between 0 and 30%; preoperative assessment of the patients’ endothelium to assess cell density may reduce postoperative complications.

Donor Cornea Evaluation

Specular microscopy is particularly important in assessment of donor corneas to assess for sufficient endothelial cell density and donor quality.<sup>21</sup>

Limitations

One of the limitations of specular microscopy is that it is difficult to image endothelial cells through edematous or opaque corneas. In these cases, confocal microscopy provides superior image quality.

**Fig. 4.2.6** Ultrasound biomicroscopy image of a patient with anterior synechiae (red arrow).

## ULTRASOUND BIOMICROSCOPY

UBM uses high frequency (20–100 MHz) ultrasound waves and is useful for the evaluation of deeper structures in the eye and in opaque corneas.<sup>14</sup> Echoes from tissues at different depths are recorded at different time intervals and can be used to construct the image. In general, higher frequency waves have lesser penetration, and lower frequency waves have lower penetration. Most UBMs in use today have scan rate of 35–50 MHz, giving an axial resolution of 42  $\mu$ m, and a depth of 4–5 mm.<sup>11,22</sup>

## Clinical Applications

Using UBM, surface epithelium, Bowman's layer, and Descemet's membrane can be identified as reflective structures, while the endothelium cannot be identified. As a result of penetration of sound through the pigmented epithelium, UBM can visualize the structures posterior to the iris, which is not possible with an AS-OCT. Hence, posterior chamber structures, including lens zonules, ciliary body, and anterior choroid, can be visualized (Fig. 4.2.6).<sup>22</sup>

### Ocular Masses

Although no imaging technique can replace histopathological examination, UBM has shown utility in the diagnosis of anterior segment tumors. Solid tumors can be identified and the extent of involvement seen.<sup>11</sup> UBM has shown superiority over AS-OCT in image quality and assessment of tumor margins and posterior surface of both pigmented and nonpigmented tumors. For evaluation of anterior surface tumor, conjunctival nevi, and anatomical relationships, AS-OCT may be superior. However, posterior shadowing with AS-OCT is not seen with UBM.<sup>11</sup> Dermoid tumors of the limbus appear as hyperreflective masses, whereas pigmented conjunctival nevi present with cysts.<sup>11</sup> For solid tumors and conjunctival melanomas, UBM can assess the margins and depth.<sup>11,22</sup>

### Glaucoma

The corneoscleral junction can be seen as a line of reflectivity change between the sclera (highly reflective) and cornea; the corneal spur is 1 mm posterior to corneoscleral junction. Hence, it can be used to assess the anterior chamber (AC) (angle, depth, and angle opening distance [AOD]), iris (thickness, distance from ciliary process, contact lens, or zonules), ciliary sulcus (diameter and distance of process from trabecular meshwork), and other angles (trabecular–iris angle, iris–lens angle, and iridocorneal angle).<sup>23,24</sup> The scleral spur may be identified manually for improved accuracy. In glaucoma evaluation, UBM has shown promise in evaluation of mechanisms underlying glaucoma, such as acute angle closure caused by pupillary block (bowed iris causing angle blockade), plateau iris (AC shallower than in controls, but deeper than in patients with pupillary block), ciliary effusion syndrome, lens dislocation/subluxation, and ciliary body masses (cyst or tumor). Postoperatively, UBM is highly useful especially if clinical examination cannot differentiate between pupillary block and malignant glaucoma. As UBM can assess anatomical relationships, it can also be used to evaluate anatomical changes with diseases.

LipiScan™ with Dynamic Meibomian Imaging™ (TearScience, Morrisville, North Carolina, USA)

**TABLE 4.2.4** Grading Systems to Assess Meibomian Gland Dysfunction

Characteristics	Grade 0	Grade 1	Grade 2	Grade 3	Grade 4
Gland dropout	None	33%	34%–66%	>66%	-
Partial glands	None	<25% of image	25%–75% of image	>75% of image	-
Loss of total meibomian gland area	None	<1/3	1/3–2/3	>2/3	-
Area of loss	0%	25%	25%–50%	51%–75%	75%

## Ocular Trauma

Because ocular trauma can present with opaque corneas or hyphema, UBM is an especially useful modality to evaluate damage to the internal structures of the eye. It can evaluate nonmetallic foreign bodies less than 1 mm that may be missed even by computed tomography (CT). Iridodiolysis can be caused with blunt trauma and is viewed as a detached iris by using UBM. A cyclodialysis cleft may be missed with gonioscopy, but a cleft that separates the ciliary body and scleral spur are evident on UBM; reattachment of ciliary body after cyclodialysis has been observed by using UBM. Because the intraocular lens vault can be seen, traumatic cataract, lens displacement, subluxation, rupture of lens capsule, and zonular damage may be seen.

## Limitations

UBM needs contact with the globe, hence patients have better tolerance to its application with topical anesthesia. It has a limited depth of penetration behind the anterior vitreous and has a limited field of view. Further, it has a relatively poor interobserver reproducibility in the assessment of AC angle, iris dimensions, and ciliary sulcus diameter.

## MEIBOGRAPHY

Meibography comprises various in vivo techniques that can study the structure of meibomian glands (MGs) and their abnormalities.<sup>25,26</sup> Traditionally, using white light and an infrared camera, meibography has evolved over time to employ infrared or near-infrared spectrum of light (wavelength 650–700 nm) and a camera with filter for infrared light or infrared-sensitive film for photography or videography. Infrared light may not be visible to the naked eye but provides high-resolution images.<sup>25,26</sup> Meibography may be employed using transillumination (contact), direct illumination (noncontact), interferometry, or by AS-OCT. In contact meibography, transilluminated MGs are seen after a fiberoptic light probe touches the palpebral surface of an everted eyelid. In noncontact meibography, the infrared light probe does not touch the lid, and a camera is used to visualize glands. This technique is more tolerable for patients because of its noncontact nature and now has been employed in various slit-lamps and other imaging devices.<sup>25–27</sup> The technique of using an AS-OCT device to view MGs is termed OCT meibography.<sup>25</sup> Ocular surface interferometers use white light, which produces a color interference pattern when it strikes the lipid–aqueous interface. This interference is quantified to assess MG structure and lipid layer thickness (LLT), as well as blink dynamics as measures of MG function.<sup>28</sup> A list of some commercially available meibography devices is given in Table 4.2.3.

## Clinical Applications

Normal MGs appear as hyperilluminated acini clusters that are surrounded by hyperilluminated ducts, adjacent to orifices and hypoilluminated areas between the MGs. The noncontact technique shows a similar image, but the contrast is inverted.<sup>29</sup> There are several classification systems in literature to assess MGs (Table 4.2.4).<sup>25</sup> These include systems based on the

**Fig. 4.2.7** (A) Meibography with anterior segment optical coherence tomography (AS-OCT) showing dysfunctional meibomian glands (MGs) (red arrow); glands are shortened, wider and do not reach the lid margin; (B–D) Lipscan images in dynamic illumination mode, adaptive transillumination mode, and dual mode, respectively; images show loss of glands (red arrows) and shortened glands that do not reach the lid margins (yellow arrows).

number of glands, percentage of partial glands, and percentage area of gland dropout (Fig. 4.2.7).<sup>27,30</sup>

### Meibomian Gland Dysfunction

The most commonly studied disease that causes an alteration of MG morphology is meibomian gland dysfunction (MGD). Viewing the MGs can help differentiate the aqueous-deficient subtype of dry eye disease (DED) from the evaporative type related to MGD. MGD can be seen on meibography as a decrease in acinar density and wall homogeneity and an increase in acinar and duct diameter.<sup>25</sup> MG dropout of the lower lid is a highly effective parameter to measure MGD as it correlates with the acinar histological findings.<sup>31,32</sup>

### Limitations

In contact meibography, patient tolerability is lower compared with non-contact meibography; topical anesthesia may need to be employed in contact meibography.

## IN VIVO CONFOCAL MICROSCOPY

IVCM allows for real-time, layer-by-layer, and near-histological resolution cellular imaging in four dimensions.<sup>33</sup> The principle of IVCM is confocality: By utilizing a white or laser light and pinhole, light is focused at a point, and reflected scattered light is deflected through a second confocal aperture.<sup>34,35</sup> Because of different indices of refraction of the various structures, different types of light scatter differently. Size, orientation, and surface of structures may influence light scatter; rough surfaces scatter beam broadly, and vice versa.<sup>35</sup> Through slicing of a tissue in various focal planes, various layers can be visualized, a concept known as “optical slicing.”<sup>34</sup> The types of IVCMs in use are discussed in Table 4.2.5. Cellular details of the cornea magnified up to 800-fold, including epithelial cells, keratocytes, endothelial cells, corneal nerves, and immune and inflammatory cells, including dendritic cells, can be viewed by laser IVCM.<sup>33,34</sup>

## Clinical Applications

### Dry Eye Disease and Neuropathic Corneal Pain

Changes from normal architecture can be seen in several corneal disorders using IVCM. With DED, epithelial and stromal changes may be viewed as

**TABLE 4.2.5** Comparison of the Types of In Vivo Confocal Microscopes

Types	HRT III with Rostock Cornea Module (Heidelberg Engineering)	Confoscan 4 (Nidek, Inc.)
Light source	670 nm laser beam	Variable slit
Objective magnification	× 63	× 40
Numerical aperture	0.95	0.75
Axial (z-axis) resolution	1 μm	26 μm
Image size	400 μm × 400 μm	460 μm × 345 μm
Stability	Applanation device provides stability	Noncontact objective lens; less stable while changing focal planes
Ease of use	Needs manual adjustment to change focal plane after 80 μm, or requires add-on joystick	User-friendly (automatic alignment and scanning)

a decrease in density of superficial and basal epithelial cells and keratocytes. Inflammation associated with DED may present with activated keratocytes (identified by increased nuclear reflectivity) and with an increase in density and activation of dendritic cells (Fig. 4.2.8A).<sup>36,37</sup> A decrease in length, number, and density of nerve fibers in subbasal nerve plexus and an increase in width, tortuosity, reflectivity, and beading can be seen in patients with DED and neuropathic corneal pain (NCP) (Fig. 4.2.8B–F).<sup>33,36</sup> Abnormal nerve regeneration with presence of microneuromas may be seen in patients with NCP.<sup>33</sup>

### Infectious Keratitis and Demodex

IVCM is a useful noninvasive tool to support the identification of various infectious agents. *Acanthamoeba* cysts and trophozoites can be visualized directly as bright reflective areas (Fig. 4.2.9A).<sup>38</sup> Filaments of *Fusarium solani*, *Aspergillus*, and *Candida* and bacterial keratitis caused by microsporidia and *Borrelia*, as well as mites, such as *Demodex*, can also be distinguished (see Fig. 4.2.9B,C).<sup>38,39</sup> Moreover, a decrease in subbasal nerve density can be observed in patients with herpetic diseases.<sup>33</sup>

### Corneal Deposits and Corneal Dystrophies

Corneal deposits, such as in amiodarone-induced keratopathy, present with bright intracellular inclusions on IVCM, whereas long, atypical and

**Fig. 4.2.8** In vivo confocal microscopy (IVCM) showing changes in the subepithelial layer (A); arrow represents dendritic cells associated with inflammation in the basal epithelium. Image of subbasal plexus showing (B) loss of nerves (*arrow*) in dry eye disease; (C) tortuosity (*arrow*); (D) nerve beading (*arrow*); (E) nerve hyperreflectivity (*arrow*) in a patient with DED; (F) microneuromas (*arrow*) in a patient with neuropathic corneal pain.

centripetal epithelial cells are seen in wave-like epitheliopathy. Different types of corneal dystrophies, although diagnosed clinically, can be assessed by IVCM, and examples are given below.<sup>40,41</sup> Epithelial basement membrane dystrophy presents with hyperreflective linear tissue and cysts in the epithelium, distorted basal epithelial cells, and abnormal subbasal nerve plexus.<sup>40</sup> Patients with Meesman's dystrophy have dark areas of the basal epithelium with bright spots and a distorted subbasal nerve plexus.<sup>40</sup> Among stromal dystrophies, lattice dystrophy is visualized as linear, branching, and ill-defined hyperreflective filaments, whereas bright round, irregular or trapezoid deposits are seen with granular dystrophy.<sup>42</sup> Among stromal dystrophies, needle-shaped hyperreflective intrastromal crystalline material are seen in Schnyder's crystalline corneal dystrophy (see Fig. 4.2.9D).<sup>43</sup> Among endothelial dystrophies, FECD presents with guttae, thick Descemet's membrane, and hyperreflective pleomorphic endothelium.<sup>40</sup>

## Limitations

IVCM has a limited field of view; several nonlapping images or image reconstruction are needed.

## TOPOGRAPHY AND TOMOGRAPHY

Corneal topography is a method of visualizing the corneal surface, and tomography involves measuring the entire corneal shape. The standard corneal topographer consists of three components: a Placido disc made up of multiple circles that can be projected onto the corneal surface, a video camera capable of capturing the reflected image of these rings, and a computer with software to digitize the resultant captured images.<sup>44</sup> The digitized image is broken down to individual points around each circle. The distance of every point is measured from the center of the Placido disc image (Fig. 4.2.10). Point-source color topographer can use color LED targets and give accurate readings with reconstruction of every single

point. Slit-scanning tomography utilizes a slit beam to visualize both the anterior and posterior corneal surfaces to assess corneal shape and thickness. Corneal power and curvature of the posterior cornea are not accurate with this technique; in addition, the power for the anterior cornea is less sensitive than that by Placido disc. Scheimpflug tomography is another technique that has a high depth of focus. Both anterior and posterior cornea, AC, and lens can be visualized. Like slit-scanning techniques, curvature differences are difficult to detect. Types of commercially available hybrid (combination) devices are given in Table 4.2.6. The resulting data are displayed as a corneal curvature maps, consisting of colors corresponding to corneal power and curvature. Steep contours are displayed as warm colors (e.g., red), whereas flat contours correspond to cool colors (e.g., green, blue). Other maps generated include refractive maps (calculate true corneal power), elevation maps (show elevation/depression at both anterior and posterior cornea in comparison to a computer-generated best-fit line; anterior surface is scaled to 10  $\mu$ m and posterior to 20  $\mu$ m), and pachymetry maps (reveal corneal thickness). When interpreting maps, it is important to be cognizant of the scale used. A standard way to present the power of the corneal surface is with the axial power map solution by using a scale whose fixed range (+30.00 to +65.50 D) is broad enough to encompass most variations in corneal curvature and whose standard contour interval (+1.50 D) will highlight only topographic features of clinical significance.<sup>45</sup> Corneal topography powers displayed are best viewed as estimates and should not be routinely used in planning cataract surgery for intraocular lens calculations.<sup>46</sup> Peripheral corneal power estimates are less precise than central measurements.

## Clinical Applications

### Refractive Surgery

Corneal topography is used primarily as a screening tool to evaluate prospective refractive surgical candidates and as a diagnostic aid in evaluating

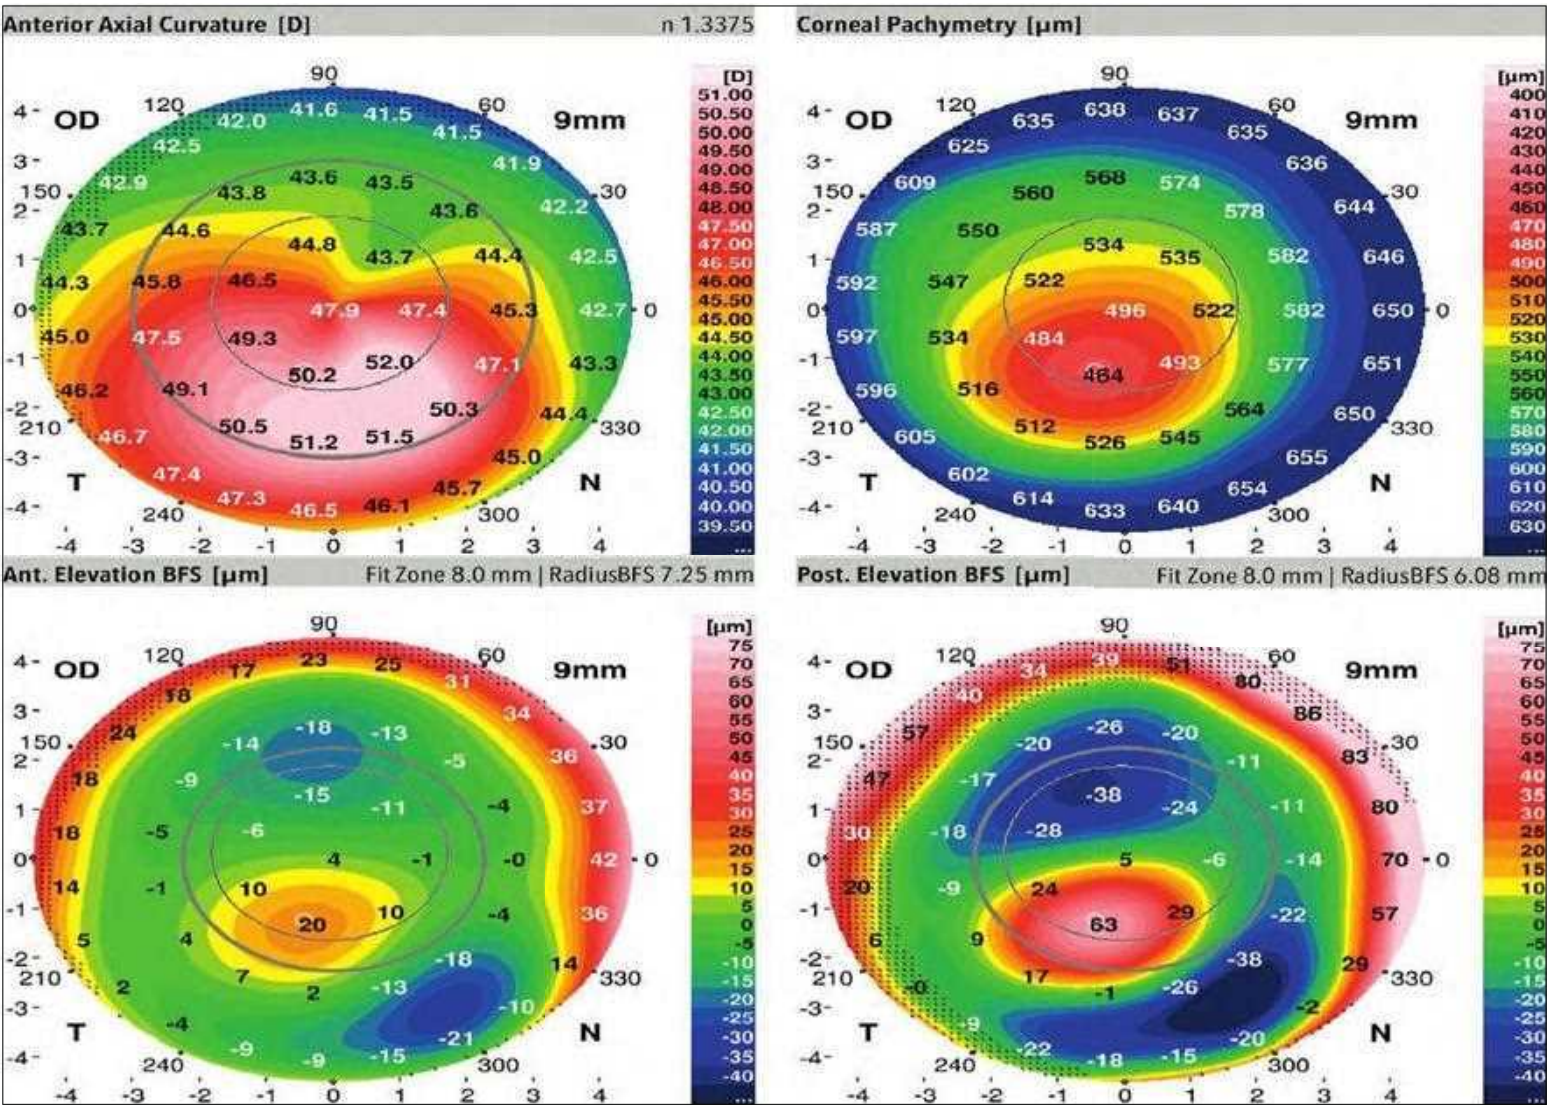

**Fig. 4.2.9** In vivo confocal microscopy (IVCM) images showing (A) *Acanthamoeba* cysts; shown with arrow, visualized as a result of a darker double wall outside the cyst; (B) *Demodex*, visualized in follicles, shown with arrow; (C) fungal filaments in the stroma, shown with arrows; (D) Schnyder's dystrophy; needle-shaped hyperreflective intrastromal crystalline material is seen.

**Fig. 4.2.10** A classic Placido disc mapped (A) in an individual with normal topography; (B) in a cornea with pellucid marginal degeneration, shows ring widening inferiorly.

**Fig. 4.2.11** Topography maps (by Galilei) of a patient with keratoconus; inferior thinning of the anterior curvature (red area) in axial map correlates with lower pachymetry and anterior and posterior elevation.

TABLE 4.2.6 A Comparison of the Types of Topography Devices				
Device	Orbscan	Pentacam	Galilei	Visante Omni
Manufacturer	Bausch & Lomb, Rochester, NY	Oculus, Inc., Wetzlar, Germany	Ziemer Ophthalmic Systems AG, Port, Switzerland	Carl Zeiss Meditec AG, Dublin, CA
System	Placido disc and slit scanning hybrid	Scheimpflug camera (50 images with 180° rotation in 2 seconds)	Dual (vertical and horizontal) Scheimpflug camera Placido hybrid	AS-OCT device (Visante) that attaches to a Placido disc device (Atlas)
Source of illumination	White light	475 nm Blue, UV free, LED	470 nm Blue, UV free, LED	1310 nm superluminescent LED
Type of system	Noncontact	Noncontact	Noncontact	Noncontact
Image size (mm)	–	5.6 × 4.5	7.4 × 7.4	10 × 3
Number of images/scan	40	25–100	15–60	512
Number of points/scan	9000–23,000	>25,000	>122,000	2048
Time of scan (sec)	1.5	2	1–2	

patients with poor vision following refractive surgery. Irregular corneas with steepening are poor candidates for refractive surgery as they are at high risk for postoperative ectasia.<sup>44,47</sup> In eyes with a history of refractive surgery, intraocular lens calculations using regular algorithms are inaccurate; topography data can help understand the new anterior–posterior corneal surface ratio.

### Ectasia-Related Disorders

Keratoconus and contact lens use are the most common causes of irregular corneas in the screening population. Steep (i.e., red) areas isolated in the inferior cornea suggest keratoconus. Many topographers come equipped with programs to alert the clinician when a diagnosis of keratoconus is likely (Fig. 4.2.11). Postoperative patients with poor vision should undergo

topography; for example, irregular ablation profiles, and decentered laser ablations can be assessed with these devices (Fig. 4.2.12).<sup>44,48</sup>

### Astigmatism

Another area where videokeratography plays an important role is the evaluation of patients with significant astigmatism.<sup>49</sup> In the past, only the anterior cornea was measured to evaluate astigmatism, but more recently, the contribution of posterior cornea has been highlighted. Topographic images can be helpful in assessing impact of conjunctival lesions, including pterygia and Salzmann’s nodular degeneration, as well as planning interventions, such as astigmatic keratotomy, limbal relaxing incisions, or removal of tight sutures after keratoplasty.<sup>50</sup> Three-dimensional images can be used to assess corneal and lens densitometry, a measure of light backscatter.

## WAVEFRONT ANALYSIS

Wavefront analysis examines the interaction of light with the optical system of an eye, giving a snapshot of the entire optical system.<sup>51</sup> With a perfect optical system, a point source of light emanating from the back of the eye creates a locus of points, with the same optical path length and in the same temporal phase, that exit the pupillary plane in the form of a flat sheet called an *unaberrated wavefront*. With imperfections in the cornea or lens, optical aberrations are created, causing the wavefront to exit as bent

or curved sheets of light. Wavefront aberration is calculated as the difference between the actual wavefront and an ideal wavefront.

Hartmann–Shack devices employ microlenslet arrays to characterize the surface of wavefronts: if the wavefront is flat, it will form a perfect lattice of points corresponding to the axis of each lenslet; if the wavefront is aberrated, it will result in a displaced spot on the grid (Fig. 4.2.13). The displacement in location, from the ideal, represents a measure of the shape of the wavefront. The complex shapes can be analyzed by deconstruction using Zernike's and Fourier's polynomial equations and basic shapes (Fig. 4.2.14).<sup>51</sup>

Wavefront maps are displayed as two-dimensional maps: green indicates minimal distortion, blue characterizes myopic wavefronts, and red represents hyperopic wavefront errors (Fig. 4.2.15A). The root mean square value quantifies the wavefront error and compares it to normal: values approaching 1  $\mu\text{m}$  for individual aberrations are considered abnormal.

## Clinical Applications

### Refractive Surgery

Wavefront technology has utility in refractive errors, especially in laser ablation for spherocylindrical errors. Traditional lasers can induce spherical aberrations; custom laser treatment that incorporates a wavefront-designed algorithm helps limit this and improves night vision (as aberrations are more pronounced with wider pupil) (see Fig. 4.2.15B).<sup>52</sup>

### Limitations

Wavefront may be affected by pupil size, vitreous or lens opacities, and the quality of the tear film. Hence, it may not be accurate in some conditions, such as DED. Additionally, the resolution of a wavefront is much lower than that of topography.

## SUMMARY

The above-mentioned modalities have clinical utility in various diseases. The choice of modality depends on the clinical experience of the physician and the area to be visualized.

**Financial Support:** NIH R01-EY022695 (PH), NIH R21-EY025393 (PH), Tufts Medical Center Institutional Support (PH). The funding organizations had no role in the design or conduct of this research.

**Conflict of Interest:** Dr. Hamrah is consultant for Heidelberg Engineering, Allergan, Eyegate Pharmaceuticals, and Dompe Pharmaceuticals.

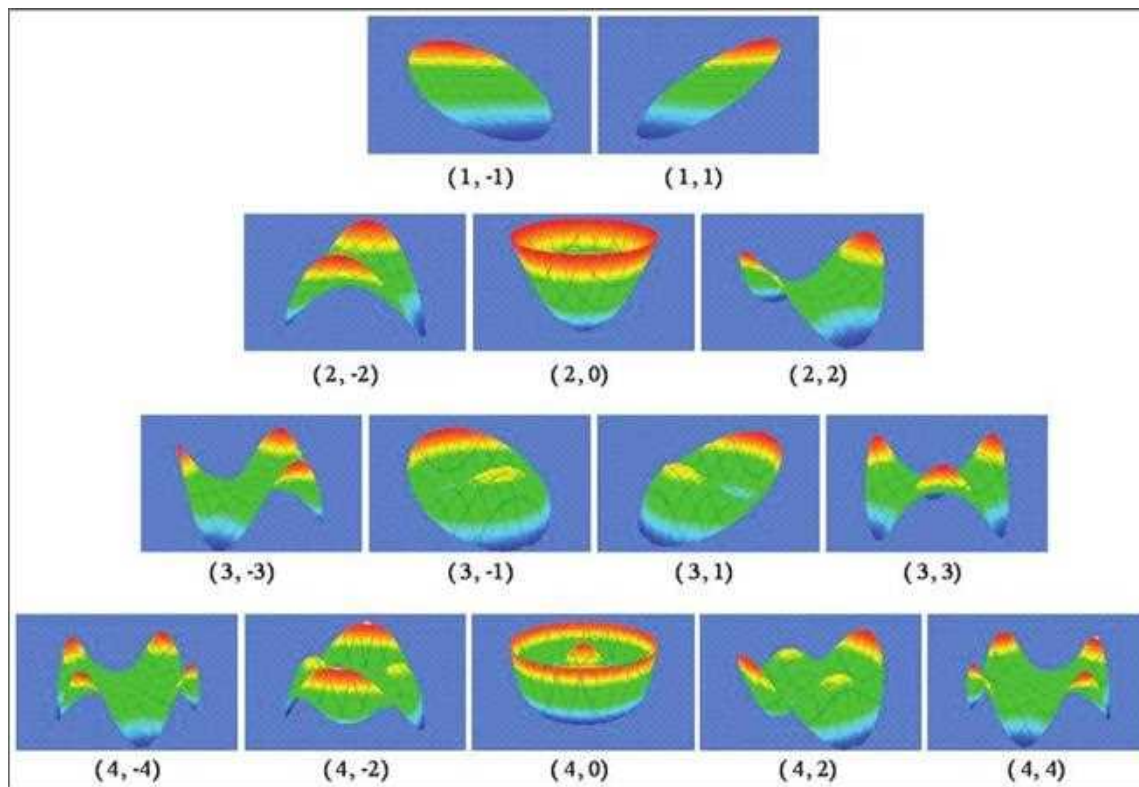

**Fig. 4.2.12** Decentered laser ablation pattern. Blue area represents laser-induced corneal flattening and the pupil is outlined with a black circle. Patients with decentered ablations may have poor vision and night vision problems such as glare or ghosting of images.

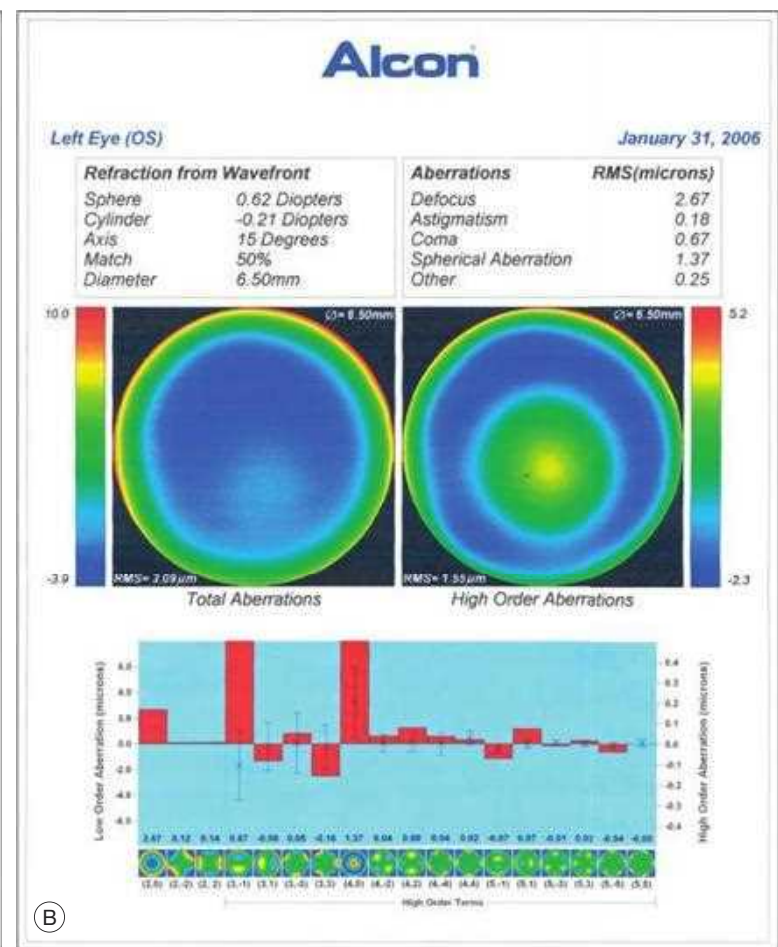

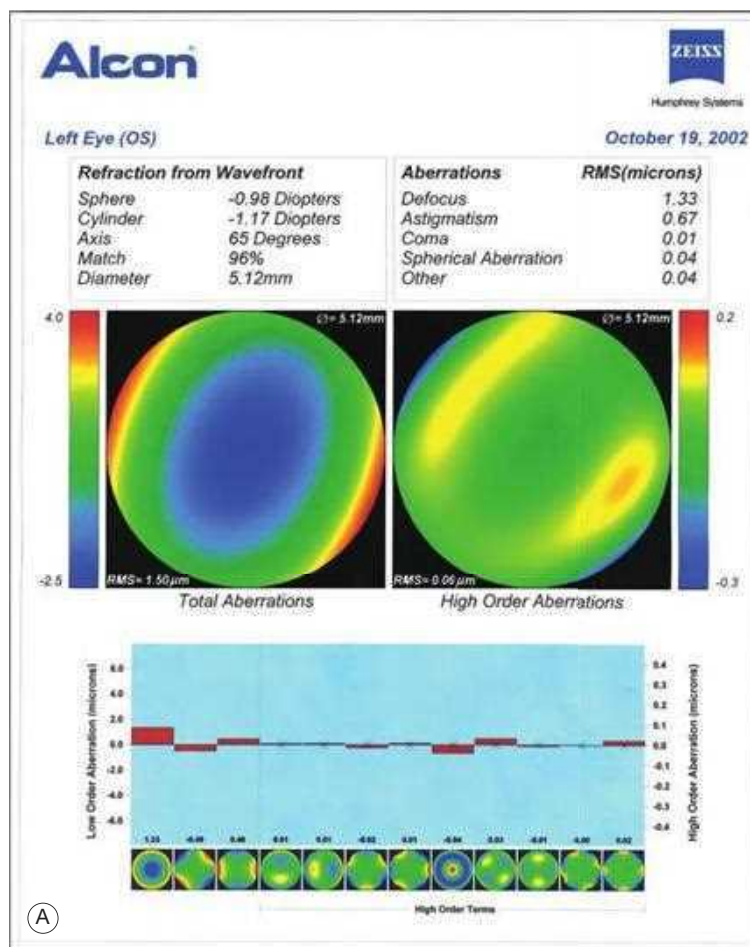

**Fig. 4.2.13** Schematic of Hartmann–Shack device used to capture wavefront data. (Courtesy AMO VISX.)

**Fig. 4.2.14** The fundamental Zernike's shapes. Complex wavefront maps can be deconstructed to determine the individual contribution of these shapes. Spherical aberration is a fourth-order term and is represented by the central figure in row 4. Coma is a third-order term and is represented by the two central figures in row 3.

**Fig. 4.2.15** (A) Normal wavefront map. The left side of the map shows total aberrations including nearsightedness and astigmatism. The right side represents higher-order optical aberrations only. (B) Wavefront map of a patient with post-LASIK night vision problems. The patient complaints are most likely caused by spherical aberration.

# Congenital Corneal Anomalies

Paula Katagiri, Kenneth R. Kenyon, Hormuz P. Wadia, Roshni A. Vasaiwala

## 4.3

**Definition:** Developmental abnormalities of the cornea present at birth.

### Key Features

- Inherited or sporadic but not acquired.
- Generally involve dysgeneses of anterior segment mesenchyme.
- Frequent association with iris, angle, and lens anomalies.

## INTRODUCTION

Developmental corneal anomalies are evident at birth, consequent to genetic, teratogenic, or idiopathic causes. During gestational week 5, as the lens vesicle separates from the surface ectoderm, the neural crest mesenchyme migrates between the surface ectoderm and the optic cup.<sup>1</sup> The first wave of mesenchyme becomes the corneal endothelium and trabecular meshwork, the second becomes corneal keratocytes, and the third becomes the anterior iris stroma. Aberrations in this process result in the anomalies of corneal size, shape, and clarity, most commonly posterior polymorphous dystrophy, Peters' anomaly, congenital glaucoma, and sclerocornea. Although pediatric keratoplasty is a challenging and complex procedure, recent series with a 40-month mean follow-up reported up to 78% graft success.<sup>2</sup> However, medical therapy remains the predominant management (52.7%) of such eyes.<sup>3</sup>

## SIZE AND SHAPE ANOMALIES

### Microcornea

The normal horizontal corneal diameter is 9.5–10 mm at birth increasing to 10–12.5 mm by adulthood. An adult cornea that is less than 10 mm horizontally is considered microcornea<sup>4</sup> and may occur in conjunction with microphthalmos, often associated with colobomas of the iris, retina, choroid, and even optic nerve (Fig. 4.3.1).<sup>5–11</sup> In contrast, nanophthalmos is a small functional eye that retains normal internal organization and proportion.

**Fig. 4.3.1**  
**Colobomatous Microphthalmos.**  
The cornea is reduced in diameter but clear and the inferior iris coloboma is typical.

### Epidemiology, Pathogenesis, and Ocular Manifestations

Most cases are sporadic, although autosomal recessive and autosomal dominant pedigrees have been reported.<sup>12</sup> In microcornea, because the remainder of the eye is normal in size, lens development may cause angle-closure glaucoma. Microphthalmos in association with dermal aplasia and sclerocornea is termed *MIDAS (microphthalmia, dermal aplasia, and sclerocornea) syndrome* (caused by deletion in Xp22).<sup>13,14</sup> An autosomal dominant variant of microcornea plus other anterior segment anomalies has been described.<sup>15</sup> Microcornea also occurs in conjunction with numerous other anomalies, including the “micro-” syndrome of microcornea, congenital cataract, mental retardation, retinal dystrophy, optic atrophy, hypogenitalism, and microcephaly.<sup>5,16,17</sup> It is also associated with fetal alcohol syndrome.<sup>18</sup>

### Treatment

Treatment involves spectacle correction for high hyperopia resulting from flat anterior corneal curvature. Other associations, such as cataract and glaucoma, are managed independently.

## Megalocornea

### Epidemiology, Pathogenesis, and Ocular Manifestations

Megalocornea with bilateral anterior segment enlargement is defined as horizontal corneal diameter of greater than 12 mm at birth or greater than 13 mm after age 2 years (Fig. 4.3.2). Most commonly associated with mutations in the *CHRD* (Xq23) gene, which encodes ventropin,<sup>19–21</sup> defective growth of the optic cup is hypothesized to leave larger space for the development of the cornea. Congenital megalocornea with childhood secondary glaucoma from spherophakia and/or ectopia lentis is a distinct condition caused by recessive *LTBP2* (14q24) mutations that must to be distinguished from buphthalmos—enlargement of the entire globe secondary to primary congenital/infantile glaucoma.<sup>22</sup>

A number of variants have been described, and of those, the autosomal dominant form without other ocular abnormalities is the least common. X-linked recessive megalocornea is more frequent and is associated with iris transillumination, pigment dispersion, lens subluxation, arcus, and central crocodile shagreen.<sup>23,24</sup> Endothelial cell density is normal, and this confirms that the enlargement does not arise from corneal stretching, and corneal clarity and thickness usually are normal.<sup>25</sup> The genetic locus for X-linked megalocornea resides in the Xq21–q22.6 region. Megalocornea has been associated with congenital miosis,<sup>26</sup> ectopia lentis, ectopia pupillae, mental retardation, congenital Marfan's syndrome, albinism, and Neuhauser's syndrome.<sup>20,27</sup> Further distinction, however, is required from megalophthalmos, a probably autosomal recessive condition, comprising an enlarged cornea in an overall enlarged eye without glaucoma, also resulting in increased axial length (often >30 mm), juvenile cataract, and high myopia.<sup>28</sup>

### Treatment

Treatment is not necessary apart for spectacle correction for myopic refractive error and for somewhat challenging cataract surgery in a much enlarged anterior segment.<sup>29</sup>

## Corneal Absence

Developmental absence of the cornea does not occur in isolation, rather as a concomitant of severe dysgenesis of the anterior segment or the entire eye. Anophthalmos—total or subtotal absence of the entire eye—is consequent to, for example, extreme developmental disorders.<sup>30–32</sup> Cryptophthalmos involves partial or complete failure of eyelid formation, corneal dermoids, and either a hypoplastic anterior segment or a rudimentary cyst-like globe

**Fig. 4.3.2 Megalocornea.** (A) The cornea is clear but enlarged to 14 mm diameter bilaterally. (B) Gross examination of postmortem specimen discloses normal cornea of large diameter and heavily pigmented trabecular meshwork probably consequent to iris pigment dispersion. (B, Courtesy Dr. M. Yanoff.)

with absence of anterior segment. Cryptophthalmos associated with systemic anomalies, such as syndactyly and genitourinary defects, is known as *Fraser's syndrome*, an autosomal recessive trait.<sup>33</sup> Pseudo-cryptophthalmos occurs when the lids fail to separate, but the underlying globe is intact.

### Congenital Anterior Staphyloma

Keratoglobus (see Chapter 4.18) is not congenital, but a more extreme corneal ectasia may be present at birth as part of congenital anterior staphyloma, often also in concert with severe variants of Peters' anomaly (Fig. 4.3.3). This anomaly is usually unilateral and frequently also presents with iris developmental defects. Anterior staphyloma may occur consequent to inflammatory or infectious corneal thinning in utero.

### ANOMALIES OF CORNEAL CLARITY

Depending on the affected wave(s) of neural crest mesenchyme migration, various corneal, angle and/or iris structures are compromised (Table 4.3.1).

#### Anterior Embryotoxon

Anterior embryotoxon represents a congenitally apparent widening of the superior limbal transition from sclera to cornea. The term also describes arcus juvenilis, an appearance similar to arcus senilis but present at birth. Although often sporadic, autosomal dominant and autosomal recessive pedigrees have been described.

**Fig. 4.3.3 Mesenchymal Dysgenesis of the Anterior Segment.** (A) Typical Peters' anomaly type I with central corneal opacity. (B) Congenital anterior staphyloma includes features of Peters' anomaly plus extreme corneal ectasia and thinning.

**TABLE 4.3.1 Relationship of Embryonic Neural Crest Migratory "Waves" to Various Anomalies**

Anomaly	Mesenchymal Wave Abnormality		
	1st	2nd	3rd
Posterior embryotoxon	x		
Axenfeld-Rieger syndrome	x		x
Peters' anomaly	x		x
Posterior keratoconus	x		
Sclerocornea		x	

### Posterior Embryotoxon

Posterior embryotoxon is highly prevalent, occurring in perhaps 24% of a random population.<sup>34</sup> It comprises thickening and anterior displacement of Schwalbe's line, most readily apparent in the temporal cornea (Fig. 4.3.4). The term *toxon*, derived from the Greek word for "bow," in reference to the crescent of Schwalbe's line, when present alone has no functional significance.

### Corneal Keloids

Keloids are white, glistening, protuberant lesions that involve all or part of the cornea. Although usually resulting from trauma or ocular inflammation, they may be evident at birth. Histopathologically comprising an irregular array of collagen, fibroblasts, and capillaries within the corneal stroma, they sometimes progress and may be associated with oculodigital disorders, such as Lowe's syndrome.<sup>35</sup> In otherwise healthy eyes, keratoplasty is appropriate.<sup>36,37</sup> For lesions where growth causes discomfort, corneal dissection with a conjunctival flap may halt progression.

**Fig. 4.3.4**  
**Posterior Embryotoxon.**  
Anteriorly displaced Schwalbe's line is evident nasally, superiorly and temporally.

## Dermoids

Dermoids are choristomas, defined as benign growths of tissue not normally present at a given location, and in the cornea they typically develop at the inferotemporal limbus where fusion of optic cup fissure occurs. At times they may involve larger areas of the cornea, the entire limbus, the entire cornea, or the interior of the eye. They usually are round, domed, pink to white to yellow in color and may have hair or, in the lipodermoid variant, globules of lipid. Depending on size, they constitute a minor cosmetic concern but may induce astigmatism or even consequent amblyopia, in which case surgical excision is indicated as also for larger lesions of anatomical and cosmetic concern. Limbal dermoids may be associated with other malformations, commonly Goldenhar's syndrome, comprising lid colobomas, hemi-facial microsomia, preauricular skin tags, and other ear anomalies (Fig. 4.3.5). Other mandibular and other facial anomalies may be concomitant and may be part of trisomy 8 mosaicism.<sup>38</sup>

Histopathology confirms the presence of skin-like collagen with skin adnexal appendages, which include hair follicles, sweat and sebaceous glands, and fat. When indicated, surgical treatment usually consists of simple superficial lamellar dissection, although the depth of the lesion, on rare occasions, requires focal lamellar keratoplasty.<sup>39</sup> Although infrequent, dermoids may involve the full thickness of the eye wall; ultrasound biomicroscopy<sup>40</sup> is useful to avoid surgical surprises. Rare spontaneous partial regression has been reported.<sup>41</sup>

## Axenfeld's Anomaly and Rieger's Syndrome

Axenfeld's anomaly comprises bilateral posterior embryotoxon often associated with iris strands adherent to Schwalbe's line (Fig. 4.3.6). Rieger's syndrome includes Axenfeld's anomaly plus iris atrophy, corectopia, and polycoria. Dental anomalies and a flattened midface and nasal bridge are common with the Axenfeld–Rieger syndrome (Fig. 4.3.7). Thus in describing this spectrum, the term *anomaly* refers to the localized anatomical changes, whereas the term *syndrome* describes more widespread ocular and systemic findings. Glaucoma occurs in about half the patients with Axenfeld–Rieger syndrome.<sup>42</sup> Seemingly, Axenfeld's anomaly and Rieger's syndrome arise from retention of neural crest remnants and primordial endothelium on the iris and chamber angle.<sup>43</sup> Defects in the *PITX2* and *FOXC1* gene on chromosome 4q25 and in the *FKHL7* gene on 6p25, as well as other defects, have been found in different patients with Axenfeld–Rieger syndrome.<sup>44,45</sup> Differential diagnosis includes iridocorneal endothelial syndrome (which is acquired and usually unilateral), posterior polymorphous dystrophy with iridocorneal adhesions, and iridogoniodysgenesis syndrome.<sup>46,47</sup>

## Peters' Anomaly

### Ocular Manifestations

Peters' anomaly comprises another mesenchymal dysgenesis condition, with most cases being sporadic but also exhibiting recessive and occasional dominant inheritance. In 80% of cases, the condition is bilateral. The manifestations are variable, with the classic type I consisting of a central

**Fig. 4.3.5** **Goldenhar's Syndrome.** Limbal dermoid (A) associated with preauricular skin tags, and ear anomalies (B).

**Fig. 4.3.6** **Axenfeld's Anomaly.** Histological section shows an iris process attached to the anteriorly displaced Schwalbe's ring (posterior embryotoxon). (Courtesy Dr. R. Y. Foos.)

corneal stromal opacity and iris strands arising from the collarette and attaching to the periphery of the opacity. Initially, a central endothelium and Descemet's membrane defect results in marked corneal edema (see Fig. 4.3.3); with time, however, the endothelium can regenerate centrally, and the edema may regress.<sup>48–50</sup> So-called posterior keratoconus and the internal ulcer of von Hippel may be considered as Peters' anomaly without iris adhesions. A type II variant has been characterized with lens adherence to the posterior cornea and/or cataract. Type I usually is unilateral, whereas type II is frequently bilateral. Other associated ocular anomalies (Fig. 4.3.8) most frequently include glaucoma in greater than 50% cases but also include microcornea, cornea plana, sclerocornea, chorioretinal

**Fig. 4.3.7 Axenfeld–Rieger Syndrome.** Polycoria with glaucoma bilaterally in a patient with dental and facial anomalies.

**Fig. 4.3.8 Mesenchymal Dysgenesis of the Anterior Segment.** This infant combines features of Peters' anomaly type II plus peripheral sclerocornea and bilateral glaucoma.

coloboma, iris coloboma, angle and iris dysgenesis, persistent hyperplastic primary vitreous, microphthalmos, optic nerve hypoplasia, and foveal hypoplasia.<sup>51</sup>

### Systemic Associations

Systemic associations include short stature, facial dysmorphism, developmental delay, and delayed skeletal maturation, constituting the autosomal recessive Krause–Kivlin syndrome. Peters' plus syndrome consists of ocular Peters' anomaly as well as syndactyly, genitourinary anomalies, brachycephaly, central nervous system anomalies, cardiac disease, or deafness.<sup>52–54</sup> Peters' anomaly may be part of fetal alcohol syndrome.<sup>55</sup> Mutations at the PAX 6 locus on chromosome 11p13 in few patients with Peters' anomaly<sup>56,57</sup> are of interest because this gene appears to be important in embryogenesis regulation and also is abnormal in aniridia and autosomal dominant keratitis.<sup>58</sup> Mutations in the *CYP11B1* gene might be causative in Peters' anomaly<sup>59</sup> because this and other gene defects (e.g., Axenfeld–Rieger syndrome, 4q25) have been implicated in ocular development as well as glaucoma.<sup>60</sup>

### Pathology

The pathology of Peters' anomaly shows absence of central Descemet's membrane and endothelium (Fig. 4.3.9), which may undergo repair over time. Other features include residual fibrosis in the opacified stroma and central absence of Bowman's layer.

### Treatment and Outcome

Primary therapy includes treatment of glaucoma, if present. Penetrating keratoplasty is clearly appropriate when corneal opacification is bilateral.

**Fig. 4.3.9 Peters' Anomaly.** Histopathological section demonstrates lens material (LM) attached to the posterior cornea. Centrally, the endothelium, Descemet's membrane, and Bowman's layer are not present. Large space (arrow) is fixation shrinkage artifact. (Courtesy Dr. M. Yanoff.)

Questioning whether keratoplasty for funicular Peters' anomaly is effective, a recent study of 14 such cases<sup>61</sup> disclosed 11 patients (78.6%) had clear grafts at 30 months' follow-up, with 10 gaining seemingly useful vision. For eyes with localized central opacity and clear midperiphery, optical iridectomy can afford a far more simplified and visually effective course. Of increasing importance to surgical decision making is the use of spectral domain–optical coherence tomography (SD-OCT) to facilitate anterior segment microstructural resolution in these complex and variable situations.<sup>62</sup> For children at high risk for keratoplasty failure, the Boston keratoprosthesis has become an alternative<sup>51</sup> because despite the challenges of long-term management, useful vision may result.<sup>63,64</sup>

### Sclerocornea

Sclerocornea defines a nonprogressive, noninflammatory scleral-like clouding of the cornea, which may be peripheral or diffuse (see Fig. 4.3.8). Resulting from defective second wave mesenchyme migration, it can cause corneal flattening or cornea plana because of limbal involvement. Sclerocornea additionally may be associated with other entities in the spectrum of anterior segment developmental defects (see Table 4.3.1), such as Peters' anomaly (see Fig. 4.3.9). Glaucoma is common, as are other systemic and ocular anomalies, as previously discussed. Inheritance may be autosomal dominant, recessive, or X-linked, although most cases are sporadic and usually bilateral. Once glaucoma has been controlled, penetrating keratoplasty or perhaps the Boston keratoprosthesis is appropriate, although outcomes usually are poor because of glaucoma and/or optic nerve anomalies.

### Congenital Hereditary Endothelial Dystrophy and Congenital Stromal Corneal Dystrophy

These two inherited corneal dystrophies are manifest at birth and, as such, comprise congenital corneal anomalies.

Congenital hereditary endothelial dystrophy appears as diffuse bilateral corneal edema in the absence of elevated intraocular pressure. Although initially held to have both autosomal dominant and recessive forms, recent evidence localizes the genetic defect to 20p13, responsible for sodium borate transport, and the recent International Committee for Classification of Corneal Diseases report<sup>65</sup> recognizes only autosomal recessive inheritance. The often-profound corneal edema results from a primary dysgenesis of the corneal endothelium with concomitant Descemet's layer changes and is appropriately considered a mesenchymal dysgenesis disorder. Rarely is intraocular pressure elevated. The results of keratoplasty generally are favorable.

Congenital stromal corneal dystrophy is a rare autosomal dominant condition resultant from a genetic defect at 12q21.33 producing abnormality of decorin.<sup>65</sup> Clinically diffuse corneal clouding results from myriad flake-like, whitish stromal opacities. Visual loss is variable, and when uncommonly indicated, keratoplasty may be successful.

# Blepharitis

Jihad Isteitiya, Neha Gadaria-Rathod, Karen B. Fernandez, Penny A. Asbell

## 4.4

**Definitions:** *Blepharitis* is a general term describing inflammation of the eyelids, whereas *marginal blepharitis* is inflammation of the eyelid margin, which can be subdivided into anterior and posterior blepharitis.

*Anterior blepharitis* involves inflammation of the lid margin anterior to the gray line and concentrated around the eyelashes and hair follicles. It may be accompanied by squamous debris, scurfs, and collarettes around the lashes. *Posterior blepharitis* involves inflammation posterior to the gray line, which may have various causes, including meibomian gland dysfunction (MGD) and conjunctivitis.

*MGD* is defined as a chronic, diffuse abnormality of the MGs, commonly characterized by terminal duct obstruction and/or qualitative/quantitative changes in glandular secretion. It may result in alteration of the tear film, symptoms of eye irritation, clinically apparent inflammation, and ocular surface disease.<sup>1</sup>

### Key Features

- Chronic burning, irritation, foreign body sensation, epiphora.
- Inflammatory changes of the eyelid including thickening, erythema, hyperkeratinization, vascularization, telangiectasia, or notching.
- Presence of scurf, collarettes, and sleeves along lashes.
- Minimal meibomian gland secretion with pressure or abnormal meibum, which is turbid, foamy, or granular in appearance.

### Associated Features

- Tylosis (thickening and distortion of the lid margin).
- Poliosis (loss of lash pigmentation).
- Punctal misdirection and/or scarring.
- Conjunctival hyperemia.
- Perilimbal superficial corneal neovascularization.
- Catarrhal infiltrates.
- Acne rosacea.

## INTRODUCTION

*Blepharitis*, first described by Elschnig in 1908,<sup>2</sup> poses a significant challenge for the clinician because of its chronic nature and availability of diverse treatment options but minimal scientific evidence for their efficacy.

Nonetheless, given the prevalence of blepharitis, its association with dry eye disease (DED), and its effect on quality of life, better understanding and management of this condition is essential for reducing ocular discomfort and improving the patient's quality of life.<sup>1</sup>

## EPIDEMIOLOGY

MGD is one of the most common disorders encountered by eyecare providers. MGD is now considered the leading cause of evaporative dry eye.<sup>1</sup>

The prevalence of MGD varies considerably in published studies, from 3.5% to almost 70%.<sup>1,3-7</sup>

This striking difference is partly attributed to inconsistent diagnostic criteria among countries and to varying age distribution between study groups.<sup>1,7</sup> The prevalence of MGD is affected by age, with older patients at increased risk of developing MGD.

## PATHOGENESIS

The pathophysiology of blepharitis involves a complex interaction of various factors, including abnormal lid-margin secretions, lid-margin organisms, and a dysfunctional precorneal tear film. Several classification systems exist for blepharitis.<sup>2,8-10</sup> It can be anatomically subdivided into anterior blepharitis (Fig. 4.4.1) and posterior blepharitis. Alternatively, blepharitis can be classified according to the presenting clinical features into staphylococcal, seborrheic, mixed staphylococcal and seborrheic, and MGD (Fig. 4.4.2).

The lid inflammation characteristic of blepharitis is most often caused by a combination of anterior and posterior factors of varying degrees. In most types of blepharitis, some MG involvement occurs.<sup>11</sup> MGs are tubuloacinar, holocrine glands that produce and secrete meibum, an oily substance that produces the lipid layer of the precorneal tear film.<sup>12</sup> Embedded in the tarsal plates, normally 30–40 MGs occur in the upper lid and 20–30 glands in the lower lid. Each MG consists of a main duct surrounded by grape-like acinar clusters. These ducts open into the lid margin just anterior to the mucocutaneous junction, delivering meibum to the tear film.

Fig. 4.4.1 Anterior blepharitis.

Fig. 4.4.2 Meibomian gland dysfunction.

MGD is defined as a chronic, diffuse abnormality of MGs, commonly characterized by terminal duct obstruction and/or qualitative/quantitative changes in the glandular secretion.<sup>9</sup> Alterations in the composition of the meibomian secretions occur in patients with chronic blepharitis.<sup>12-14</sup> Alteration in nonpolar lipids raises the melting point of the meibum, leading to thickening of the meibum and stagnation. Decreased amounts of polar lipids result in uneven spreading of tears,<sup>15</sup> likely leading to instability of the tear film and hyperosmolarity, increased bacterial growth, evaporative dry eye, and ocular surface inflammation, including keratinization, scarring, and retraction of the gland orifices, thus further exacerbating MGD. Several factors can aggravate MGD, such as increasing age, contact lens wear, and hormonal imbalance.<sup>10,11,14</sup>

Several bacteria, fungi (*Pitysporum*), and parasites (*Demodex*) also have been implicated. The most common organisms isolated from patients with chronic blepharitis include *Staphylococcus epidermidis*, *Propionibacterium acnes*, corynebacteria, and *Staphylococcus aureus*.<sup>16</sup> *S. epidermidis* and *S. aureus* produce lipolytic enzymes, such as triglyceride lipase, cholesterol esterase, and wax esterase, which hydrolyze wax and sterol esters with the release of highly irritating free fatty acids, resulting in the disruption of the tear film integrity.<sup>12</sup> In seborrheic blepharitis, the increased amount of low viscosity meibum favors the growth of bacteria and leads to inflammation of the lids.<sup>14</sup> Acne rosacea is a relatively common chronic skin disease characterized by persistent erythema, telangiectasis, papules, pustules, and sebaceous gland hypertrophy, predominantly affecting the forehead, cheeks, and nose. Although the pathogenesis is still unclear, studies suggest that it is primarily caused by an altered innate immune response in those with a genetic predisposition. Certain reactive oxygen species and infectious agents, such as *Demodex folliculorum* and *Helicobacter pylori* also have been implicated.<sup>17</sup>

## OCULAR MANIFESTATIONS

Typical symptoms of blepharitis include redness, itching, burning, crusting along the lid margin, loss of lashes, stickiness of lashes, and tearing. Furthermore, as MGD has been suggested to be the leading cause of DED,<sup>1</sup> presenting symptoms, such as dryness, ocular irritation, and fluctuating vision, may indicate the need for the clinician to examine the lid margin. These symptoms are chronic, usually waxing and waning, and may be exacerbated by some environmental factors, such as wind, smoke, dust, cosmetic products, and so on. Symptoms usually are bilateral but may be asymmetrical. The presence of predominantly unilateral symptomatology should alert the clinician to consider other diagnoses, such as sebaceous cell carcinoma, which may masquerade as chronic unilateral blepharitis.

External examination using slit-lamp biomicroscopy is essential in establishing diagnosis and determining the type of blepharitis. Staphylococcal anterior blepharitis is more common in the younger population and has a female preponderance. Findings include vascularization and erythema of the lid margin, telangiectasia, eyelid edema, loss or misdirection of lashes, collarettes around the base of the lashes, and crusting or hyperkeratosis. Chronic findings of ulceration, punctal misdirection, and scar formation may be seen. There can be signs of corneal involvement in severe cases, presenting with phlyctenulosis, corneal neovascularization, thinning, or marginal ulceration. Seborrheic blepharitis is more common in the older age group. It presents with *scurf*s, which is a term used to refer to the scales, oily debris, and greasy material that collects along the lash shaft as a result of hypersecretion from MGs.<sup>18</sup> In blepharitis associated with *Demodex* sp. infestation, the most commonly seen finding is coating of the lash with cylindrical dandruff-like material (sleeves).<sup>19</sup>

Clinical signs of MGD may include rounding, thickening, and irregularity of the eyelid margin; changes in the lid vascularity and presence of telangiectasia; pouting, plugging, and narrowing of the gland orifices; reduction in volume and number of glands secreting liquid; and changes in gland secretion quality, clarity, and viscosity with greater pressure required to express secretions.<sup>19,20</sup> "Non-obvious MGD" is a common form of obstructive MGD that shows no obvious signs of inflammation, hypersecretion, or purulent secretion of the glands but may become more apparent with pressure on the lid as the meibum orifices are examined.<sup>21</sup> In chronic MGD, there may be cicatricial changes along the lid margin, and the mucocutaneous junction may migrate anterior to the MG line.<sup>22</sup> Subtle signs, such as the frothy quality of the tear meniscus, and decreased Schirmer's scores and tear breakup time (TBUT), may be found. Other ocular conditions, such as recurrent chalazia, trichiasis, and keratoconjunctivitis sicca, may be seen. External examination of the face and skin may reveal associated dermatological problems, such as seborrheic dermatitis, atopy, herpes zoster ophthalmicus, and acne rosacea. In ocular

rosacea, dilated and telangiectatic vessels at the lid margin and interpalpebral hyperemia may be seen.

## DIAGNOSIS AND ANCILLARY TESTING

Blepharitis is mainly a clinical diagnosis. However, ancillary testing may be considered in those who have chronic disease or are unresponsive to therapy, to monitor treatment effect, and for research purposes.

Culture samples taken from the eyelid margins may grow the typical bacteria associated with blepharitis, as well as viruses, such as herpes simplex, herpes zoster, and molluscum contagiosum. Microscopic examination of the epilated lashes may show *Demodex* eggs, and adult mites.<sup>18</sup>

MG secretion can be analyzed by its quality and expressibility. This can be done by digital pressure or with the use of a device that applies a standard pressure that is equivalent to the pressure exerted on the lids during a normal blink.<sup>23</sup> This device targets a standard area of one third of the total number of glands (8–10 glands). Expressibility is graded according to the number of glands that express fluid; decreased expressibility indicates disease. Although it sounds simple, marked variability exists among individuals, and hence a definite cutoff between normal and abnormal cannot be defined. Moreover, the location of the glands along the lid margin influences their expressibility. It was found that nasal glands tend to express most actively, followed by central glands, and then temporal glands.<sup>24</sup> The quality of glandular secretion can be evaluated in terms of appearance. It can be classified as clear, cloudy opaque, viscous, or toothpaste-like by using various grading schemes.<sup>21,25</sup>

More recently, interferometry has been developed to measure the lipid layer of tears. The patient's eye is illuminated with light directed at the corneal surface; light passes through the tear film and is reflected into a camera, forming an interference pattern called an *interferogram*. The interferometer measures the lipid layer thickness of a defined area of tear film and captures the blink profile during a designated time interval. A positive correlation between tear film lipid layer thickness and expressible MGs suggests that a low lipid layer thickness indicates a high probability of MGD.<sup>26</sup>

Changes in MG morphology and gland dropout can be assessed using meiboscopy. This is done with transillumination through the skin and observing the glandular silhouette through the everted mucosal side. Photodocumentation of the same is called *meibography*.<sup>18</sup> The disadvantage of the transillumination method is that it may be tedious and time consuming. Noncontact meibography applies the same principle but is easier and more rapid than transillumination. It uses an infrared transmitting filter attached to a slit lamp and video camera.<sup>27</sup> Photographs are taken, and MG morphology and dropout are then analyzed. Recent advancements to the technology now include mobile, handheld, pen-shaped systems with an infrared light-emitting diode fixed to the camera, which enables capturing of videos and images that are comparable in quality with previous meibography systems. It is convenient and applicable for examination of MGs in patients of all ages.<sup>28</sup>

Keratography permits visual assessment of the topography of the corneal surface, allowing for an analysis of tear film stability by comparing the irregularities in recorded images. In addition to evaluating TBUT, keratography can examine MGs, tear meniscus height, and lipid layer.<sup>29</sup>

In vivo laser scanning confocal microscopy is a contact technique can be used to examine the microstructure of MG acinar units and measure their size.<sup>30</sup>

## TREATMENT

The goal of all the treatments of MGD is to improve the flow of meibomian gland secretions, thus achieving normal tear film stability.<sup>31</sup>

Treatment strategies aiming at improving the quality of the meibum include a combination of lid hygiene, management of MGD, reducing bacterial colonization of the lids, suppression of inflammation, and restoring tear quality.<sup>32</sup> It is crucial to educate patients about the chronic, recurrent nature of the disease and the need for long-term intervention. Despite the availability of diverse treatment options, very few treatments have been extensively evaluated for safety and efficacy in randomized controlled trials, and most are typically not approved by the U.S. Food and Drug Administration (FDA) for use in blepharitis specifically. Treatment recommendations are largely dependent on clinical experience and published case reports.

Lid hygiene, the mainstay of treatment for blepharitis, consists of warm compresses, lid massage, lid scrubs, and avoidance of excessive eye makeup. Treatment with warm compresses involves the placement of a

warm washcloth on closed lids daily for 5–10 minutes. The goals of heat therapy are to soften and loosen encrustations, liquefy the solidified and stagnant secretions, and to dilate ducts. This is followed by lid massage. The eyelid is held taut at the outer corner with one hand while the index finger of the other hand sweeps from the inner corner of the lid toward the ear while applying pressure. This is repeated several times to express the MG contents, which have melted during the warm compresses step. Cleansing with lid scrubs is usually done once or twice daily initially. Commercially available scrubs or a cotton-tipped applicator soaked with a weak solution of baby shampoo can be used to rub along the lid margin to remove deposits and the abnormal oily secretions from the lids. Patients should be instructed to avoid excessive scrubbing and massage because these actions can lead to ocular irritation.

Besides self-care, therapeutic MG expression as an in-office procedure performed by the clinician can help relieve MGD by using probes and/or mechanical pressure to open and express meibum. Intraductal MG probing is a relatively nontraumatic method that utilizes small stainless steel probes to open the MG orifices, and this may mechanically open and dilate the natural orifices and ducts of the MGs.

Participants currently are being recruited for a randomized, double-blind trial investigating the efficacy of intraductal MG probing compared with a sham procedure in patients with refractory MGD.<sup>33</sup> However, therapeutic expression may be painful to the patient.<sup>34</sup> The BlephEx device, a less invasive method of microexfoliation of the lid margins, utilizes a rapidly rotating microspoon to remove lid debris and microbial biofilm from the lid margins.<sup>35</sup> Recently, a new thermopulsation device has been developed, and it allows heat to be applied to the palpebral surfaces of the lids directly over the MGs while simultaneously applying graded pulsatile pressure to the outer eyelid surfaces, thereby gently expressing MGs during heating. The automated treatment device has two main components: a lid warmer and an eye cup. The lid warmer resembles a large oval scleral lens designed to rest on the bulbar conjunctiva and vault the cornea. The eye cup contains an inflatable air bladder that massages the eyelids to express MGs in the upper and lower eyelids simultaneously.<sup>36</sup>

Topical antibiotics are added when underlying bacterial infection is suspected. Bacitracin and erythromycin ophthalmic ointments are effective agents for anterior blepharitis. Generally, ointments are applied directly to the lid margins to avoid toxicity to the ocular surface. Fluoroquinolone eyedrops have minimal ocular toxicity and have a wide coverage of organisms. Topical fusidic acid has shown efficacy in patients with ocular rosacea blepharitis. Although not yet approved by the FDA, topical metronidazole gel 0.75%–1% also may be effective when used on the lid margin for treatment of ocular rosacea.<sup>32</sup> Systemic antibiotics, such as cloxacillin, may be added for treatment of persistent or recurrent staphylococcal blepharitis. Oral tetracyclines are commonly used in the management of rosacea and MGD. They are mainly used for their anti-inflammatory and lipid-regulating properties, rather than for their antimicrobial effects. They decrease the production of bacterial lipases, thus reducing the concentration of free fatty acids and their deleterious effects on lipid composition.<sup>37</sup> They exert anti-inflammatory effects resulting from inhibition of matrix metalloproteinases, cytokines, lymphocyte and neutrophil activation, and chemotaxis. They also have antiangiogenic and antiapoptotic properties.<sup>38</sup> They usually are used in doses ranging from 250 mg once to four times a day (tetracycline and oxytetracycline) to 50–100 mg once or twice a day (doxycycline and minocycline). Low doses of doxycycline 20 mg may be used when long-term therapy is required. A 40 mg/day slow-release dose of doxycycline is approved for treatment of rosacea and is used by some clinicians. Tetracycline use is limited by its common side effects, which include sun sensitivity and gastrointestinal upset and known contraindications for use in pregnant women and children. Oral macrolide antibiotics, such as erythromycin and azithromycin, are safer and also have immunomodulatory and anti-inflammatory effects similar to those of tetracyclines. Recently, the use of a topical azithromycin (1%) was suggested as an effective treatment of posterior blepharitis, with a significant improvement in MG secretion quality, eyelid redness, tear quality, and overall symptomatic relief, but results from studies regarding efficacy are mixed.<sup>39</sup>

In cases with more severe lid margin inflammation, a short-term course of topical corticosteroids or antibiotic–corticosteroid combinations may be utilized. Long-term use of corticosteroids is limited by serious side effects, such as cataracts, glaucoma, and infection. Topical immunomodulators, such as cyclosporine A 0.05%, a calcineurin inhibitor, have been shown to be beneficial in the treatment of MGD in conjunction with rosacea and/or DED, with a significant improvement in lid margin inflammation and signs of DED.<sup>40</sup> Nearly all suggested treatments have not received FDA approval for use in lid disease.

As change in tear composition and tear film stability may be a key contributor to lid margin inflammation, supplementation of the tear film may improve both MGD and DED. Treatment options include tears, gels, ointments, environmental control, and moisture goggles. A newer class of tear substitutes involving the use of lipid-containing eyedrops, liposomal sprays, emulsion-type eyedrops, and ointments that may be more effective than saline-based artificial tears in DED associated with MGD.<sup>41,42</sup> Dietary supplementation with omega-3 fatty acids has been shown to be effective in improving signs and symptoms of DED and MGD by reducing ocular surface inflammation and improving the lipid composition of meibum.<sup>11</sup>

Several additional methods of treatment exist that have been found to be helpful when used in conjunction with the core interventions mentioned above. Antiseborrheic shampoos, such as those containing selenium sulfide or tar, may be helpful when seborrheic dermatitis is significant. Weekly lid scrubs with 50% tea tree oil and daily lid scrubs with tea tree shampoo are effective in eradicating *Demodex* infestation of the lids but can be irritating to the ocular surface.<sup>43</sup> As MGD may be related to androgen deficiency or receptor dysfunction, topical androgens are being evaluated as a possible therapeutic option for patients with MGD.<sup>44</sup>

A growing interest exists in the role of blepharitis, especially MGD, in understanding and treating ocular surface disease, especially DED. However, to date, there is still limited understanding of what findings are clinically pathological and associated with signs and symptoms of ocular disease and what treatments would most benefit patients. Current research is addressing environmental, dietary, pharmacological, and surgical interventions to better understand blepharitis and to optimize the treatment of this chronic ocular condition.

# Herpes Zoster Ophthalmicus

Majid Moshirfar, Gene Kim, Brian D. Walker, Orry C. Birdsong

# 4.5

**Definition:** Infection of varicella (chickenpox) in the ophthalmic division of the trigeminal dermatome most frequently affecting the nasociliary branch.

## Key Features

- Herpes zoster ophthalmicus can affect any of the ocular or adnexal tissues.
- Treatment with antivirals promotes healing of rashes and prevents ocular complications.

## Associated Features

- Postherpetic neuralgia.

## EPIDEMIOLOGY AND PATHOGENESIS

Herpes zoster (zoster, shingles) is a neurocutaneous disease caused by human herpes virus 3 (HHV-3), the same virus that causes varicella (chickenpox). It is a member of the herpes virus family (Herpesviridae) and exclusively infects human or simian cells. Varicella zoster virus (VZV) is the smallest of the alphaherpes viruses and has very stable linear double-stranded DNA. It has an icosahedral capsid and lipid envelope, which contains glycoproteins for cell entry.<sup>1</sup>

Herpes zoster has the highest incidence of any neurological disease, with an annual occurrence of approximately 1 million cases in the United States.<sup>2</sup> The lifetime risk is about 30%, and 50% of those living until 85 years of age will be affected.<sup>2-5</sup> The reported incidence varies from 3.2 to 4.2 per 1000 individuals per year. Increased risk of developing zoster is associated with older age (incidence of 10 per 1000 individuals over 80 years) and immunosuppression.<sup>6</sup>

In temperate climates, primary infection with this virus usually occurs before age 10 years, manifesting clinically as chickenpox (varicella). The virus then establishes a latent state in the sensory ganglia. In circumstances of diminished virus-specific and cell-mediated immunity, the virus may reactivate and spread to the corresponding dermatome along a spinal or cranial nerve to generate the characteristic unilateral vesicular exanthem. The accompanying inflammation of the sensory nerve and skin damage are purportedly responsible for the acute pain.<sup>7,8</sup>

Physical trauma and surgery have been correlated with the development of zoster.<sup>9-12</sup> Other reported triggers include tuberculosis, syphilis, radiation therapy, and corticosteroids.<sup>13</sup>

The epidemiology of zoster ultimately is dependent on the transmission and spread of VZV in a population. The spread of primary varicella (chickenpox) infection is of primary importance, but latent and reactivated infections play an important role in maintaining VZV infections within a population. Latently infected older adults and immunosuppressed patients are important reservoirs of the virus, as these groups are more likely to experience reactivation. When zoster does occur, the virus can be transmitted to a seronegative individual during the vesicular phase of the rash and cause a primary varicella infection. A zoster exposure with a seropositive, latently infected individual may result in a subclinical reinfection and boost humoral and cellular VZV immunity but is unlikely to cause acute varicella or herpes zoster.<sup>14</sup> Herpes zoster may develop in immunocompetent patients who harbor the latent virus and who are re-exposed to it by contact with someone who has active varicella or zoster infection (primary, spontaneous, or infectious zoster).<sup>13,15,16</sup>

## Ophthalmic Herpes Zoster

The frequency of herpes zoster ophthalmicus (HZO) is second only to thoracic dermatomal occurrence, with up to 250 000 cases occurring yearly in the United States.<sup>4,17</sup> Of these, 50%–70% suffer visual morbidity with severity increasing in the 5th–8th decades of life.<sup>4,17</sup> The virus most commonly establishes latency in the trigeminal sensory ganglion and reactivates in 10%–25% of the population.<sup>17</sup> The ophthalmic division of the trigeminal nerve is affected 20 times more frequently than the maxillary or mandibular divisions.<sup>18</sup> Ocular involvement occurs in more than 70% of patients with zoster of the first (ophthalmic) division of the trigeminal nerve. Nasociliary branch involvement with skin lesions located on the inner corner of the eye, tip of the nose (Hutchinson's sign), and root or side of the nose is predictive (50%–85%) of ocular involvement and is strongly prognostic for ocular inflammation and corneal sensory denervation.<sup>13,19</sup> The eye may be seriously affected in up to 50% of cases in the absence of Hutchinson's sign.<sup>20</sup>

HZO usually begins with a prodrome of influenza-like illness, which is characterized by fatigue, malaise, nausea, and mild fever; this is accompanied by progressive pain and skin hyperesthesia, which is characterized by a burning painful area along a specific dermatome, followed by a diffuse erythematous or maculopapular rash that appears 3–5 days later. These eruptions can progress to form clusters of papules and clear vesicles and evolve through stages of pustulation, vesiculation, and crusting. Patients with deeper involvement of the dermis may develop permanent scars with loss of normal pigmentation. Rarely, herpes zoster may manifest with ophthalmic symptoms in the absence of cutaneous eruptions.<sup>8,21</sup>

## CLINICAL MANIFESTATIONS

HZO may affect all ocular and adnexal tissues and manifest with a diverse array of signs and symptoms. Ocular or extraocular involvement may occur at the time of the cutaneous eruptions or years later.

The skin of the forehead and upper eyelid is commonly affected and strictly obeys the midline with involvement of the ophthalmic division of the trigeminal nerve (Fig. 4.5.1). Zoster involves the deep dermis, in contrast to herpes simplex, which is limited to the epidermis. Deep involvement may cause numerous lid complications, such as scarring, entropion, and ectropion. Conjunctival findings include hyperemia, petechial hemorrhages, papillary or follicular reaction, or, rarely, pseudo-membrane. Episcleritis and scleritis are common and tend to progress toward the limbus, causing vasculitis and sterile corneal infiltrates.<sup>22</sup>

Corneal pathology tends to result from three pathophysiological mechanisms: (1) active viral infection; (2) immune-mediated inflammation; and (3) chronic neurotrophic keratopathy. Active viral infections tend to affect the epithelium, leading to punctate epithelial keratitis and pseudo-dendrites (Fig. 4.5.2). Pseudo-dendrites are typically smaller than typical dendrites, and lack terminal end-bulb formations. Immune-mediated stromal keratitis can take multiple forms. Nummular keratitis is the earliest finding of corneal stromal involvement and presents during the second week of the disease in 25%–30% of patients.<sup>22</sup> It is characterized by multiple, fine, granular, coin-shaped infiltrates in the anterior stroma and may cause permanent scarring. Chronic interstitial keratitis may lead to deep corneal neovascularization and lipid keratopathy. Disciform keratitis is a deep stromal infiltrate that develops 3–4 months after the acute phase, characterized by a central disc-shaped area of diffuse corneal edema that results from endotheliitis and anterior chamber inflammation. Perilimbal vasculitis from immune-complex deposition can lead to sterile, peripheral, anterior cornea stromal infiltrates.

Active zoster infections travel through branches of the ophthalmic division of the cranial nerve.<sup>6</sup> Each reactivation damages the corneal nerves

**Fig. 4.5.1** Herpes zoster ophthalmicus involving the V1 distribution.

**Fig. 4.5.2** Peripheral corneal epithelial pseudo-dendrites in a patient with a history of herpes zoster ophthalmicus. (Courtesy Hu AY, et al. Late varicella-zoster virus dendriform keratitis in patients with histories of herpes zoster ophthalmicus. *Am J Ophthalmol* 2010;149:214–20 e3.)

causing progressive neurotrophic keratopathy. Late-stage HZO gives the picture of chronic epitheliopathy with filamentary keratitis and anterior stromal scars from a compromised ocular surface. The risk of secondary bacterial infection may be high in this setting.<sup>20</sup>

HZO can cause nongranulomatous or granulomatous iridocyclitis (anterior uveitis) with keratic precipitates. It often has a chronic course, necessitating topical corticosteroids for control. Specific signs include elevated intraocular pressure from trabeculitis and sectoral, vasoocclusive iris atrophy. Glaucoma from HZO is often multifactorial. An early cause is from trabeculitis that resolves with corticosteroids, but chronic

inflammation leads to pupillary seclusion, chronic angle-closure glaucoma, and, possibly, corticosteroid-response glaucoma.

Posterior segment manifestations of HZO include retinal perivascularitis, ischemic optic neuropathy, and forms of necrotizing retinopathy. These complications are uncommon but vision threatening. Two forms of retinitis are worth noting: acute retinal necrosis (ARN), which tends to occur mainly in immunocompetent patients, and progressive outer retinal necrosis (PORN), which occurs mainly in immunocompromised patients. ARN tends to present with severe ocular inflammation, whereas PORN appears less inflamed but has a much faster and vision-threatening clinical course.<sup>22</sup> PORN is characterized by multifocal, deep retinal lesions that rapidly progress to confluence with minimal or no intraocular inflammation, an absence of vascular inflammation, and perivenular clearing of retinal opacification.<sup>20</sup>

External ocular motor palsies frequently occur in acute HZO. Infections may affect the third, fourth, and sixth cranial nerves. These complications are thought to be from vasculitis within the orbital apex and frequently resolve within a year.

## Postherpetic Neuralgia

Pain that continues following rash healing has been termed *postherpetic neuralgia* (PHN). Pain in HZO has three phases: (1) acute pain—first 30 days during and after rash onset; (2) subacute herpetic neuralgia—between 30 and 120 days; and (3) PHN when greater than 120 days.<sup>23,24</sup>

PHN can occur in any patient with HZO; however, it usually is not seen in patients less than 50 years of age, and its frequency increases until age 70 years. It afflicts about one half of all patients with herpes zoster who are older than 70 years and appears to be more severe in older patients.<sup>13</sup> The pain may occasionally be so extreme and persistent that some patients consider suicide.<sup>13</sup> Risk factors for PHN include greater acute pain severity,<sup>24,25</sup> greater rash severity,<sup>26,27</sup> and presence of a painful prodrome preceding the rash.<sup>28</sup> Additional risk factors for PHN include older age and female gender.<sup>23</sup>

## HERPES ZOSTER OPHTHALMICUS IN ACQUIRED IMMUNE DEFICIENCY SYNDROME

HZO is an important early clinical marker for acquired immunodeficiency syndrome (AIDS), especially in high-risk younger patients.<sup>29–31</sup> Immunocompromised patients have a higher incidence, greater severity, and more prolonged course of ocular involvement, as well as PHN, compared with immunocompetent patients with HZO.<sup>32</sup> All nonpregnant, young patients with HZO should be tested for human immunodeficiency virus (HIV). PORN is reported with increasing frequency in patients with AIDS. Following cytomegalovirus retinopathy, PORN is the second most frequent opportunistic retinal infection in patients with AIDS in North America.<sup>33</sup>

## DIAGNOSIS

The diagnosis of herpes zoster disease generally is based on clinical findings, although in recent decades, the clinical manifestations and spread of VZV have shifted. This change may confound clinical impressions (e.g., HSV lesions may appear to be zosteriform and be difficult to differentiate from zoster). Differential diagnosis includes eczema herpeticum, eczema vaccinatum, impetigo contagiosum, enterovirus-associated exanthema, contact dermatitis, drug eruptions, and insect bites.

Cytological examination of cutaneous vesicular scrapings reveals multiple eosinophilic intranuclear inclusions (Lipschutz's bodies) and multinucleated giant cells (Tzanck's preparation). Specimens (cutaneous vesicular scraping or conjunctival swab) must be transported to the laboratory as quickly as possible under low temperature conditions (4 °C).<sup>33</sup> Immune electron microscopy techniques using specific peroxidase-labeled monoclonal antibodies against specific virus antigens can directly detect VZV.<sup>34</sup> VZV-DNA can be obtained via anterior chamber paracentesis or vitreous tap and analyzed using real-time polymerase chain reaction.<sup>35</sup> Fluorescent antibody techniques, cytospin direct immunofluorescence staining, and rapid direct immunofluorescence assays (SimulFluor direct fluorescent antibody) are additional methods for detecting VZV.<sup>36</sup>

Serological tests to detect herpes zoster antibodies are of limited use because cross-reactivation between VZV and HSV can occur. Following zoster infection, a booster of IgG is detected for 2 weeks and then falls to lower levels and could persist at that level for years.<sup>37</sup>

## MANAGEMENT

HZO is treated with oral antivirals: acyclovir, famciclovir, or valacyclovir. Acyclovir (800 mg, five times daily for 7–10 days), reduces viral shedding and the chance of systemic dissemination, and reduces the incidence and severity of ocular complications, particularly if used within 72 hours of onset of symptoms.<sup>38,39</sup> Acyclovir also can shorten the duration of pain if taken within the first 3 days of onset of symptoms.<sup>40,41</sup> Intravenous acyclovir is recommended in immunocompromised patients.<sup>38,42</sup>

Famciclovir (500 mg, three times daily for 7 days) is a prodrug of penciclovir and has a much higher bioavailability (77%) compared with acyclovir (18%). It has been shown to be well tolerated and safe with similar efficacy to acyclovir.<sup>43</sup>

Valacyclovir (1000 mg three times daily for 7 days) is the L-valine ester of acyclovir and has higher bioavailability (80%) compared with acyclovir (18%). It has similar activity to acyclovir in the prevention of the sequelae of herpes zoster and has been shown to be as effective in preventing ocular complications of HZO. Comparative analysis also has shown that tolerability of the two drugs was similar.<sup>44</sup> Valacyclovir has been shown to significantly accelerate the resolution of pain compared with acyclovir.<sup>45</sup> Comparisons between valacyclovir and famciclovir treatment in HZO have not shown significant difference in resolution of pain or rash.<sup>46</sup>

Of note, acute renal failure rarely has been reported with these medications, especially intravenous administration.<sup>47,48</sup> As a result, kidney function should be monitored closely and renal dosing guidelines followed when appropriate. Dosing for children should be executed with reference to appropriate dosing guidelines. Acyclovir and valacyclovir are thought to be safe for use during pregnancy.<sup>49</sup>

### Management of Ocular Manifestation

Palliative therapy, including Burow's solution, cool compresses, mechanical cleansing of the involved skin, and topical antibiotic ointment without corticosteroid, are helpful in treating skin lesions.

Oral acyclovir has been shown to be effective for the punctate, pseudo-dendritic, and delayed corneal mucous plaque forms of herpes zoster epithelial keratitis.<sup>40,41</sup> Debridement may be helpful.

Neurotrophic keratitis or epithelial defects associated with herpes zoster keratitis may be treated with nonpreserved artificial tears, eye ointments, punctal occlusion, pressure patching, or therapeutic soft contact lenses. If these measures are unsuccessful, tarsorrhaphy, conjunctival flap, or autologous conjunctival transplantation should be considered. Studies have shown that good results can be achieved with corneal transplantation in patients with a history of HZO.<sup>50</sup>

Topical corticosteroids are useful in the management of sclerokeratitis, keratouveitis, interstitial keratitis, anterior stromal infiltrates, and disciform keratitis.<sup>22</sup> Corticosteroids generally should not be used in cases of exposure or neurotrophic keratitis because of the possibility of keratolysis.<sup>22</sup> Topical cycloplegics prevent ciliary spasm associated with herpes zoster inflammatory disease. Aqueous suppressants and topical corticosteroids should be used to treat HZO glaucoma. Herpes zoster vitritis, vitreous hemorrhage, and vitreous debris may respond to topical, periocular, or systemic corticosteroids. Herpes zoster infections affecting the cranial nerves are best treated with a combination of systemic corticosteroids and intravenous acyclovir. Retinitis (ARN and PORN) is best treated with a combination of intravitreal injections and valacyclovir.<sup>51</sup>

### Postherpetic Neuralgia

Postherpetic neuralgia is challenging to control and may be treated with analgesics, tricyclic antidepressants (nortriptyline, amitriptyline, desipramine, clomipramine), and anticonvulsants (carbamazepine and phenytoin), often in combination. Newer medications (e.g., gabapentin—ranging from 300 mg three times daily to 1200 mg three times daily; and pregabalin) are more effective than tricyclic antidepressants against treating allodynia, another subtype of neuralgia.<sup>52</sup> Capsaicin cream (0.025%) is effective when applied to the involved skin three to four times daily, although 2

weeks of treatment is often required for pain relief.<sup>53</sup> PHN may be severe, intractable, and permanent, with some patients requiring psychiatric and pain clinic care, and occasionally trigeminal rhizotomy or stellate ganglion block may occur.<sup>54</sup>

Findings of a meta-analysis reveal that famciclovir and valacyclovir significantly reduce the duration but not the incidence of PHN. Studies have shown corticosteroids to have no beneficial effect in the treatment of PHN.<sup>55,56</sup> Amitriptyline for 90 days reduced the incidence of pain at 6 months. Finally, a single trial of percutaneous electrical nerve stimulation (PENS) in 50 patients reported decrease in pain incidence at 3 and 6 months compared with famciclovir.<sup>57</sup>

## PREVENTION

The varicella vaccine is available in two formulations which are both given subcutaneously: Varivax (Merck) and Zostavax (Merck). The former prevents primary varicella infections in infants, and the latter prevents reactivation of zoster in adults. Both utilize live attenuated virus. Differences in administration are that Zostavax is only administered once and has 14 times the concentration of Varivax, which is given twice.<sup>58</sup>

Studies have shown that Zostavax reduces the incidence of zoster by 50%, PHN by 60%, and HZO by 49% and that it reduces the severity of illness in those with reactivation of the virus.<sup>59,60</sup> The efficacy of all three vaccine measures has been shown to decrease as time after vaccination increases.<sup>61</sup> The most common adverse effect is pain and erythema at the injection site with equivalent rates of adverse events of 1.4% for the vaccine and placebo group.<sup>62</sup> The vaccinated group, however, did have a higher rate of serious adverse events. Case reports in the literature describe exacerbation of chronic HZO, exacerbation of uveitis, new-onset retinitis in immunocompromised patients, and dermatological and disseminated disease after Zostavax administration in patients with a history of HZO.<sup>58,63–71</sup> Despite these reports and possible risks, a history of HZO is currently not a contraindication to the vaccination.

The Centers for Disease Control and Prevention and the Advisory Committee on Immunization Practices recommend that the zoster vaccine be administered to adults age 60 years and above for the prevention of herpes zoster, including those who have already had a case of zoster.

# Conjunctivitis: Infectious and Noninfectious

# 4.6

Jonathan B. Rubenstein, Tatyana Spector

**Definition:** Conjunctivitis is infectious or non-infectious inflammation of the mucous membrane lining eye wall and inner lids.

### Key Features

- Infectious causes may be bacterial, fungal parasitis, or viral.
- Infectious conjunctivitis can be classified by duration of symptoms.
- The diagnosis is usually made clinically. If the diagnosis is not readily apparent, laboratory studies may be helpful in determining etiology.
- May be noninfectious causes of conjunctivitis.

## INFECTIOUS CONJUNCTIVITIS

### Bacterial Infections

Bacterial conjunctivitis is characterized by a rapid onset of unilateral conjunctival hyperemia, lid edema, and mucopurulent discharge. The second eye typically becomes involved 1–2 days later.

The pathogenesis of bacterial conjunctivitis usually involves a disruption of the host defense mechanisms, for example, abnormalities of the ocular surface secondary to eyelid abnormalities, tear film abnormalities, or systemic immunosuppression.<sup>1,2</sup> Bacterial conjunctivitis can be classified into three clinical types: acute, hyperacute, and chronic (see Table 4.6.1 for a list of common pathogens).<sup>1</sup>

Conjunctival membranes and pseudo-membranes may occur in bacterial conjunctivitis in association with *Neisseria gonorrhoeae*,  $\beta$ -hemolytic streptococci, and *Corynebacterium diphtheria*. Pseudo-membranes, which include inflammatory cells and an exudate containing mucus and proteins, are loosely adherent to the underlying conjunctival epithelium and can be peeled away with no bleeding or damage to the epithelium. True membranes occur with more intense inflammation. The conjunctival epithelium becomes necrotic, and firmer adhesions are formed between the necrotic cells and the overlying coagulum. When the membrane is peeled, the epithelium tears to leave a raw, bleeding surface.

### Acute Bacterial Conjunctivitis

Acute bacterial conjunctivitis usually begins unilaterally with hyperemia, irritation, tearing, mucopurulent discharge, and matting of the lids (Fig. 4.6.1). Punctate epithelial keratitis also may occur. The most common pathogens include *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*.<sup>1</sup> Other common ocular manifestations include blepharitis, keratitis, marginal ulcers, and phlyctenulosis.<sup>3</sup> The pathogens *H. influenzae*, *S. pneumoniae*, and *Moraxella catarrhalis* occur more commonly in young children and may occur in institutional epidemics.<sup>4</sup> *H. influenzae* is often associated with systemic infection, including upper respiratory infections, and acute otitis media.

The treatment of acute bacterial conjunctivitis consists of topical antibiotic drops or ointments. Although these infections normally are

self-limiting, lasting 7–10 days, antibiotic therapy usually speeds the resolution and lessens the severity of the disease. A broad-spectrum antibiotic with good Gram-positive coverage, such as a third- or fourth-generation fluoroquinolone, 10% sodium sulfacetamide, or trimethoprim-polymyxin, may be used for 7–10 days.

### Hyperacute Bacterial Conjunctivitis

The most common cause of hyperacute bacterial conjunctivitis is *N. gonorrhoeae*.<sup>1</sup> This oculo-genital disease is seen primarily in neonates and sexually active young adults. Transmission is by contact with infected urine or genital secretions. Symptoms develop within 24 hours, and signs include profuse, thick, yellow-green purulent discharge, painful hyperemia, chemosis of the conjunctiva, and tender preauricular nodes. Untreated cases may lead to peripheral corneal ulceration and eventual perforation with possible endophthalmitis. A similar, but milder form of conjunctival and corneal disease is caused by primary or secondary infection with *Neisseria meningitidis*. Primary meningococcal conjunctivitis is extremely rare in adults and can be invasive (followed by systemic meningococcal disease) or noninvasive (isolated conjunctival infection).<sup>5</sup> If invasive disease is present, close contacts should receive prophylaxis with a single dose of ciprofloxacin 500 mg or rifampin 600 mg twice daily for 2 days.<sup>6</sup>

Treatment is directed at the specific pathogen. Conjunctival scraping for Gram staining and culture on blood and chocolate agar are strongly recommended. Gram-negative diplococci are suggestive of *Gonococcus*. An effective regimen for gonococcal conjunctivitis is a single dose of 1 g of intramuscular ceftriaxone. If a corneal ulcer is present, hospitalization with 1 g intravenous ceftriaxone for 3 days is recommended. Topical medications may include bacitracin, ciprofloxacin, or erythromycin ointment every 1–2 hours. Frequent irrigation, every 30–60 minutes, with normal saline or balanced salt solution, also is recommended. Adults are often treated empirically for concurrent chlamydial infection with azithromycin 1 g once or doxycycline 100 mg twice a day for 7 days.<sup>7</sup> In meningococcal conjunctivitis, systemic treatment includes intravenous penicillin, or for penicillin-resistant infections, intravenous cefotaxime or ceftriaxone.<sup>5</sup> Patients need to be seen daily to rule out corneal involvement.

**Fig. 4.6.1 Acute Bacterial Conjunctivitis.** This patient was culture-positive for *Pneumococcus*.

**TABLE 4.6.1 Pathogens That Cause Bacterial Conjunctivitis**

Acute	Hyperacute	Chronic
<i>Staphylococcus aureus</i>	<i>Neisseria gonorrhoeae</i>	<i>Staphylococcus aureus</i>
<i>Streptococcus pneumoniae</i>	<i>Neisseria meningitidis</i>	<i>Moraxella lacunata</i>
<i>Haemophilus influenzae</i>		Enteric bacteria

**Fig. 4.6.2 Staphylococcal Marginal Keratitis.** Note the inferior marginal corneal ulcers and the blepharoconjunctivitis.

### Chronic Bacterial Conjunctivitis

Chronic bacterial conjunctivitis, lasting longer than 3 weeks, may result from a number of organisms and is often associated with blepharitis. The most common organisms are *S. aureus* and *Moraxella lacunata*; other causative organisms include the enteric bacteria *Proteus mirabilis*, *Escherichia coli*, *Klebsiella pneumoniae*, *Serratia marcescens*, and *Branhamella catarrhalis* from the upper respiratory tract.<sup>1</sup> The most common causative agent is *S. aureus*, which colonizes the eyelid margin and then causes direct infection of the conjunctiva or conjunctival inflammation through its elaboration of exotoxins.<sup>8</sup> Chronic angular blepharoconjunctivitis of the inner and outer canthal angles most commonly results from *M. lacunata*. A chronic follicular conjunctivitis may accompany both types.

The clinical signs of chronic staphylococcal conjunctivitis include diffuse conjunctival hyperemia with papillae or follicles, minimal mucopurulent discharge, and conjunctival thickening. Erythema of the eyelid, telangiectasis, lash loss, collarettes, recurrent hordeolae, and ulcerations at the base of the cilia can be seen. The cornea may demonstrate marginal corneal ulcers (Fig. 4.6.2).

Treatment combines proper antimicrobial therapy and good lid hygiene, which includes warm compresses and eyelid scrubs. Azithromycin drops and erythromycin or bacitracin ointments are effective adjunctive topical antibiotics. When severe inflammation exists, antibiotic and corticosteroid combination drops or ointments can be rubbed into the lid margins after the lid scrubs. Oral therapy with tetracycline 250 mg four times a day, doxycycline 100 mg one to two times a day, or minocycline 50 mg one to two times a day may be needed for more severe infections.

### Adenoviral Conjunctivitis

Viral conjunctivitis is extremely common. The diagnosis usually can be made clinically.<sup>8</sup> Many different viruses cause conjunctivitis, and each produces a slightly different disease.

Adenoviruses produce the most common viral conjunctivides with varying degrees of severity. The spectrum consists of follicular conjunctivitis, pharyngoconjunctival fever, and epidemic keratoconjunctivitis. These infections are spread via respiratory droplets or direct contact from fingers to the lids and conjunctival surface. The incubation period is usually 5–12 days and the clinical illness is present for 5–15 days.<sup>9</sup>

#### Follicular Conjunctivitis

Follicular conjunctivitis is the mildest form and is associated with adenovirus serotypes 1 through 11 and 19.<sup>10</sup> It has an acute onset and is initially unilateral with possible involvement of the second eye within 1 week. It is manifested by a watery discharge and conjunctival hyperemia and usually is accompanied by follicular and papillary conjunctival changes with preauricular lymphadenopathy on the affected side. Most cases resolve spontaneously, without sequelae, within days to weeks.

#### Pharyngoconjunctival Fever

Pharyngoconjunctival fever is the most common ocular adenoviral infection<sup>11</sup> and is produced by adenovirus serotypes 3, 4, and 7. It is characterized by a combination of pharyngitis, fever, and conjunctivitis (Fig.

**Fig. 4.6.3 Acute Bilateral Viral Conjunctivitis.** This 22-year-old man has pharyngoconjunctival fever, and the conjunctivitis was preceded by a viral upper respiratory tract infection.

**Fig. 4.6.4 Epidemic Keratoconjunctivitis.** Early pseudo-membrane formation may be seen in the inferior fornix.

4.6.3). The conjunctivitis is predominantly follicular with a scant watery discharge, hyperemia, and mild chemosis. The cornea may be involved with a fine punctate epitheliopathy. Preauricular lymph nodes are enlarged in about 90% of cases. The disease resolves spontaneously within 2 weeks, so treatment is usually supportive with cold compresses, artificial tears, and judicious use of vasoconstrictor eyedrops.

#### Epidemic Keratoconjunctivitis

Epidemic keratoconjunctivitis (EKC) is produced by adenovirus serotypes 8, 19, and 37. It is a more severe type of conjunctivitis and typically lasts for 7–21 days. EKC produces a mixed papillary and follicular response of the conjunctival stroma with a watery discharge, hyperemia, chemosis, and ipsilateral preauricular lymphadenopathy (Fig. 4.6.4).<sup>8,11</sup> Subconjunctival hemorrhages, conjunctival membrane formation, and lid edema are common (see Fig. 4.6.4; Fig. 4.6.5).<sup>10</sup> Histologically, these conjunctival membranes consist of fibrin and leukocytes with occasional fibroblast infiltration. Both true membranes and pseudo-membranes may occur, and conjunctival scarring and symblepharon formation may follow their resolution.

Corneal involvement is variable. Most patients have a diffuse, fine, superficial keratitis within the first week of the disease. Focal, elevated, punctate epithelial lesions that stain with fluorescein develop by days 6–13 (Fig. 4.6.6), producing a foreign body sensation. By day 14, subepithelial opacities develop under the focal epithelial lesions in 20%–50% of cases (Fig. 4.6.7). These opacities often are visually disabling and may persist for months to years, but eventually they resolve with no scarring or vascularization.<sup>12</sup> The diagnosis of EKC is made clinically, but a rapid immunodetection assay (RPS Adeno Detector; Rapid Pathogen Screening; South

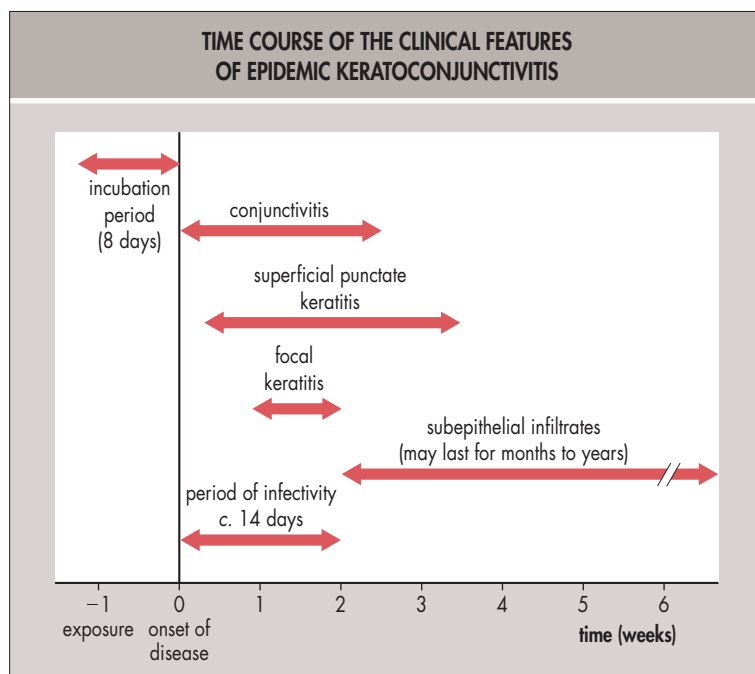

**Fig. 4.6.5 Pseudo-Membrane in Epidemic Keratoconjunctivitis.** An early pseudo-membrane is forming in the inferior fornix.

**Fig. 4.6.6 Epidemic Keratoconjunctivitis Subepithelial Infiltrates.** These infiltrates develop 2 weeks after the onset of the disease and persist for months to years.

**Fig. 4.6.7** Time course of the clinical features of epidemic keratoconjunctivitis.

Williamsport, PA) is now available and is capable of detecting all 53 adenoviral serotypes with a reported sensitivity of 89% and specificity of 94%.<sup>13</sup>

Treatment aims at alleviation of symptoms and minimization of transmission of this highly contagious disease. Patients may be infectious for up to 14 days after onset.<sup>10,14,15</sup> and outbreaks are especially common in ophthalmology offices and clinics. Transmission usually occurs from eye to fingers to eye; tonometers, contact lenses, and eyedrops are other routes of transmission. Preventive measures include frequent hand washing, relative isolation of infected individuals in an office setting, and disinfection of ophthalmic instruments.<sup>16,17</sup> During the stage of acute conjunctivitis, treatment usually is supportive and includes cold compresses and decongestant eyedrops. When patients have decreased visual acuity or disabling photophobia from subepithelial opacities, topical corticosteroid therapy may be beneficial. High-dose topical corticosteroids, such as 1% prednisolone acetate three to four times a day, or difluprednate twice a day, can help eliminate subepithelial infiltrates.<sup>18</sup> However, some believe that use of topical corticosteroids prolongs viral shedding and worsen symptoms if the infectious virus is herpes simplex. Cidofovir, an antiviral agent, has been investigated in the treatment of EKC.<sup>19,20</sup> Although the application of cidofovir drops may prevent the formation of corneal opacities, use has been limited by local toxicity and commercial unavailability. Others have advocated the use of topical gancyclovir. Currently, the utility of a povidone-iodine 0.4%/dexamethasone 0.1% combination ophthalmic suspension is being investigated.<sup>21</sup>

### Acute Hemorrhagic Conjunctivitis

Acute hemorrhagic conjunctivitis, also known as *Apollo disease*, was first described in Ghana in 1969.<sup>22</sup> Two picornaviruses, enterovirus 70 and coxsackievirus A24, are the usual causative agents.<sup>23,24</sup> Less commonly, it is caused by adenovirus type 11. A rapid onset of severe, painful follicular conjunctivitis occurs, with chemosis, tearing, lid edema, and tiny subconjunctival hemorrhages. The hemorrhages are petechial at first and then coalesce, appearing posttraumatic. The cornea may demonstrate a fine punctate keratopathy and, rarely, subepithelial opacities. The conjunctivitis resolves within 4–6 days, but the hemorrhages clear more slowly. The disease occurs in epidemics, especially in developing countries, with more than 50% of the local population affected in some cases. Very rarely, cases caused by enterovirus type 70 can result in a polio-like paralysis, which remains permanent in up to one third of affected individuals.

### Herpes Simplex Conjunctivitis

Primary herpes simplex conjunctivitis usually occurs in children under 5 years of age. Most cases are undocumented because of their nonspecific nature. Typical signs include ocular irritation, watery discharge, mixed papillary and follicular conjunctivitis, hemorrhagic conjunctivitis, and preauricular lymphadenopathy.<sup>25</sup> Most cases are unilateral but may become bilateral. Epidermal vesicular eruptions of the eyelids and lid margins may accompany the conjunctivitis (Fig. 4.6.8), and the cornea may be involved. Corneal involvement may include a coarse, punctate epithelial keratitis, marginal infiltrates, or a dendritic ulcer. Although herpetic blepharconjunctivitis is associated mainly with the primary disease, it may occur as a manifestation of recurrent disease with or without typical herpetic keratitis.<sup>25</sup> Most ocular herpetic infections result from herpes simplex virus type 1. Infections that result from the type 2 serotype may be seen in newborns or adults who have a history of oral–genital contact.<sup>26</sup>

The conjunctivitis usually resolves spontaneously in 7–14 days without treatment,<sup>25</sup> although some physicians administer topical antiviral drops to patients with corneal involvement or to patients with lid vesicles, with the goal of preventing corneal involvement. Care should be taken to avoid the cavalier use of corticosteroids in the treatment of patients who have an acute follicular conjunctivitis because some of these patients may have herpetic disease and corticosteroids may enhance the severity of herpetic epithelial keratitis.

### Other Causes of Viral Conjunctivitis

Other causes of viral conjunctivitis include the rubella, rubeola, varicella-zoster, Epstein–Barr virus infection, Newcastle disease, and Zika virus infections.<sup>23</sup> Rubella virus produces a nondescript, catarrhal follicular conjunctivitis associated with the systemic disease. Rubeola produces a catarrhal, papillary conjunctivitis with tearing, pain, and photophobia. Pale, discrete, avascular spots, which resemble Koplik's spots seen in the mouth, may appear on the conjunctiva. Varicella-zoster virus produces pustules and phlyctenule-like lesions on the conjunctiva, and a follicular

**Fig. 4.6.8 Primary Herpes Simplex Blepharoconjunctivitis.** Note the bilateral vesicular eruptions in this child who has a primary herpes simplex infection.

**Fig. 4.6.9 Giemsa Staining of a Conjunctival Scraping.** The epithelial cells show basophilic cytoplasmic inclusions typical of a chlamydial infection.

#### BOX 4.6.1 Causes of Chronic Follicular Conjunctivitis

- Chlamydiasis
- Trachoma
- Adult inclusion conjunctivitis
- Molluscum contagiosum
- Drug-induced or toxic conjunctivitis
- Bacterial conjunctivitis
- Axenfeld's chronic follicular conjunctivitis
- Merrill–Thygeson-type follicular conjunctivitis
- Parinaud's oculoglandular syndrome
- Folliculosis of childhood

conjunctivitis may occur with recurrent skin disease. Follicular conjunctivitis associated with the Epstein–Barr virus occurs in association with infectious mononucleosis.<sup>27</sup> Newcastle disease viral conjunctivitis occurs in poultry workers and veterinarians in whom direct conjunctival inoculation of the virus has occurred while handling infected birds.<sup>28</sup> The disease is self-limiting, lasts 7–10 days, and leaves no ocular sequelae. Zika virus is a mosquito-borne infection that has led to many outbreaks in Africa and Asia, and most recently, in 2015, it has reached the Americas. The virus may present with fever, rash, arthralgia, and conjunctivitis in approximately 20% of cases. Symptoms are generally self-limiting, although fetal transmission may lead to brain defects.<sup>29</sup>

### Chronic Follicular Conjunctivitis

Chronic follicular conjunctivitis lasts more than 16 days (Box 4.6.1).<sup>8</sup> *Chlamydia trachomatis*, an obligate intracellular bacterium, is the most common cause; it causes three clinical syndromes—trachoma, adult inclusion conjunctivitis, and neonatal conjunctivitis.

#### Trachoma

Trachoma, which results from *C. trachomatis* serotypes A to C, is endemic in many parts of the world, including Africa, the Middle East, Latin America, Central Asia, and South-East Asia.<sup>30</sup> Current reports indicate that active trachoma affects approximately 150 million people worldwide, with about 10 million people developing secondary trichiasis and approximately 6 million blinded from sequelae of the disease. After an incubation period of 5–10 days, trachoma manifests as a mild, mucopurulent conjunctivitis that is typically self-limiting and heals without permanent sequelae.<sup>31</sup> Repeated infections, however, result in chronic inflammation, including follicular conjunctivitis and papillary hypertrophy of the upper palpebral conjunctiva, a superior superficial corneal pannus, and fine epithelial

keratitis. Eventually, multiple reinfections lead to scarring and cicatrization of the cornea, conjunctiva, and eyelids.

The trachoma complications that cause blindness occur as a result of corneal ulceration, severe conjunctival scarring, and eyelid deformities with their concomitant effects on the ocular surface.<sup>32</sup> Arlt's line (a horizontal line that results from conjunctival scarring at the junction of the anterior one third and posterior two thirds of the conjunctiva) is a characteristic finding on the superior pretarsal conjunctiva. Herbert's pits are a unique sequelae of trachoma<sup>33</sup>; these sharply delineated depressions occur after necrosis and cicatrization of limbal follicles, and the resultant clear space is filled with epithelium. A diffuse haze of the superior cornea may result after regression of the superior pannus. Eyelid deformities, such as trichiasis, distichiasis, entropion, and ectropion, all may occur. Corneal complications, including scarring, vascularization, ulceration, and perforation, lead to decreased visual acuity and possible blindness.

Treatment of trachoma usually consists of a 3- to 4-week course of oral tetracycline (tetracycline 1 g/day or doxycycline 100 mg/day) or oral erythromycin. The clinical response may be slow and take 9–18 weeks to be seen. More recently, a single 20 mg/kg dose of oral azithromycin has been shown in several randomized controlled trials to be as effective as 6 weeks of topical tetracycline.<sup>31,34,35</sup> Topical azithromycin 1.5% twice daily for 2–3 days has also been found to be as effective as the single oral dose with a low recurrence rate.<sup>36</sup> Widespread repeated use of systemic antibiotics in endemic areas has been tried in an attempt to eradicate the disease with slow resolution of active trachoma.<sup>37</sup>

#### Adult Inclusion Conjunctivitis

Adult inclusion conjunctivitis results from *C. trachomatis* serotypes D to K. It presents as a unilateral red eye with mucopurulent discharge, marked hyperemia, papillary hypertrophy, and a predominant follicular conjunctivitis. A tender, enlarged preauricular lymph node is common. Women often have a concomitant vaginal discharge secondary to a chronic cervicitis, and men may have symptomatic or asymptomatic urethritis. The conjunctivitis is often chronic, lasting many months. Keratitis may develop 1 week after onset. Corneal involvement includes a superficial punctate keratitis, small marginal or central infiltrates, EKC-like subepithelial infiltrates, limbal swelling, and a superior limbal pannus. The untreated disease has a chronic course, and keratitis or iritis can occur in the later stages of the disease.

Diagnosis is based on the clinical appearance plus laboratory test results. Basophilic intracytoplasmic epithelial inclusions are seen with Giemsa staining of conjunctival scrapings (Fig. 4.6.9). Immunofluorescent staining of the conjunctival scrapings is also useful. Serum immunoglobulin G titers to *Chlamydia* may be obtained.

The modes of transmission include orogenital activities and hand-to-eye spread of infective genital secretions. The incubation period is 4–12 days. One in 300 patients who have genital chlamydial disease develops adult inclusion conjunctivitis.<sup>38</sup> It is important to treat all sexual partners simultaneously to prevent reinfection and also to rule out other venereal diseases, such as gonorrhea and syphilis. Treatment consists of systemic antibiotics, as topical antibiotics are relatively ineffective in the treatment of the eye disease. A single 1-g dose of azithromycin or doxycycline 100 mg twice a day for 7 days is the recommended treatment. Tetracyclines should be avoided in children younger than 7 years of age and in pregnant or lactating women.

**TABLE 4.6.2 Causes of Neonatal Conjunctivitis**

Causes	Time of Onset (Postpartum)
Chemical (povidone-iodine)	1–36 hours
Chlamydia	5–14 days
<i>Neisseria gonorrhoeae</i>	24–48 hours
Bacteria ( <i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Haemophilus</i> , <i>Moraxella</i> , <i>Escherichia coli</i> , <i>Pseudomonas</i> )	2–5 days
Virus (herpes simplex virus types 1 and 2)	3–15 days
The cause of the conjunctivitis is established by the clinical picture, time course, and laboratory confirmation.	

**TABLE 4.6.3 Guidelines for Treatment of Neonatal Conjunctivitis**

Infection	Treatment
Chlamydia	Oral erythromycin 50 mg/kg/day in four divided doses for 14 days
<b>Bacteria</b>	
Gram-positive	Erythromycin 0.5% ointment four times a day
Gram-negative, gonococcal	Intravenous or intramuscular ceftriaxone 25–50 mg/kg single dose
Gram-negative, others	Gentamicin or tobramycin ointments
Viral	Trifluorothymidine drops every 2 hours for 7 days

## Neonatal Conjunctivitis (Ophthalmia Neonatorum)

Conjunctivitis of the newborn is defined as any conjunctivitis that occurs within the first month of life (Table 4.6.2).<sup>39</sup> It may be a bacterial, viral, or chlamydial infection or a toxic response to topically applied chemicals. Because the infectious agent may produce a severe localized infection of the eye plus a potentially serious systemic infection, precise identification of the cause is essential.

Not all infants exposed to infectious agents in the birth canal develop conjunctivitis; the duration of the exposure is an important factor in the development of disease. Prevention with good prenatal care and treatment of chlamydial, gonococcal, or herpetic infections during pregnancy significantly lower the incidence of neonatal conjunctivitis. Proper eye cleaning using sterile cotton followed by the instillation of erythromycin or tetracycline antibiotic ointments immediately after birth helps prevent neonatal ocular infection. Previous studies suggested that instillation of 2.5% povidone-iodine as prophylaxis has superior bactericidal effects and also is active against viruses, most notably herpes simplex.<sup>40</sup> However, recent studies suggest topical tetracycline and erythromycin ointment may be more effective in prevention of ophthalmia neonatorum given that 5%–10% of patients treated with povidone-iodine developed a chemical conjunctivitis.<sup>41,42</sup>

### Chlamydial Infections

The most frequent cause of neonatal conjunctivitis in the United States is *C. trachomatis*. Infants whose mothers have untreated chlamydial infections have a 30%–40% chance of developing conjunctivitis and a 10%–20% chance of developing pneumonia.<sup>43</sup> Symptoms typically develop 5–14 days after delivery and may be unilateral or bilateral. Initially, infants have a watery discharge that may progressively turn mucopurulent. Signs include lid edema, a papillary conjunctival response, and pseudo-membrane formation (Fig. 4.6.10). Usually, the infection is mild and self-limiting; severe cases, however, may occur and result in conjunctival scarring and a peripheral corneal pannus with corneal scarring. If either erythromycin or tetracycline ointment is applied within 1 hour of delivery, the chance of developing chlamydial conjunctivitis is markedly decreased.<sup>44</sup>

Laboratory data are very helpful in the diagnosis. Enzyme-linked immunosorbent assay is nearly 90% sensitive and over 95% specific and provides results within several hours. A direct immunofluorescent monoclonal antibody stain of conjunctival smears is the most useful serological test because it has over 95% sensitivity and 77%–90% specificity for *Chlamydia*, depending on the prevalence of the disease. It may show infections missed by other assays and can be read immediately. Polymerase chain reaction (PCR) and ligase chain reaction also are available and are approximately 90% sensitive and 100% specific.<sup>45</sup>

Topical therapy alone is not sufficient to treat chlamydial conjunctivitis. The recommended treatment is oral erythromycin syrup 50 mg/kg/day in four divided doses for 14 days (Table 4.6.3). If complete response does not

**Fig. 4.6.10** A 10-day-old infant who has unilateral conjunctivitis. The mother had an untreated chlamydial infection of the birth canal.

occur, a second course of the same therapy may be given. The mother and her sexual partners should be treated with oral azithromycin 1 g in a single dose or oral amoxicillin 500 mg three times daily for 7 days.<sup>46</sup>

### Neisserial Infections

Neonatal conjunctivitis caused by *N. gonorrhoeae*, a Gram-negative diplococcus that can penetrate an intact epithelium, has decreased significantly since the advent of prophylactic agents. The clinical picture of gonococcal conjunctivitis consists of the development of a hyperacute conjunctivitis 24–48 hours after birth characterized by marked eyelid edema, profound chemosis, and excessive purulent discharge. The discharge often is so copious that it reaccumulates immediately after the eye has been wiped clean. Conjunctival membrane formation may occur. Because the organism may penetrate an intact epithelium, corneal ulceration with possible perforation can occur if the conjunctivitis is not treated adequately.<sup>47</sup>

Diagnosis is made by identification of Gram-negative intracellular diplococci on conjunctival smears. The organism is best cultured on chocolate agar or Thayer–Martin agar incubated at 37 °C in 10% carbon dioxide, and sensitivities should be obtained. Prompt diagnosis by examination of immediate Gram staining is essential to timely and effective therapy.

Local treatment consists of aqueous penicillin G drops 10 000–20 000 units. Drops are given every hour with a loading dose of one drop every 5 minutes for 30 minutes. Systemic therapy also should be instituted with intravenous or intramuscular ceftriaxone 25–50 mg/kg in a single dose (see Table 4.6.3). For disseminated disease, consultation with an infectious disease specialist is recommended. The mother and her sexual partners should be treated with intramuscular ceftriaxone 250 mg in a single dose.

### Other Bacterial Infections

Many different organisms can cause bacterial neonatal conjunctivitis. Bacteria are probably transmitted through the air to the infant shortly after birth and may be associated with nasolacrimal duct obstruction. These infections are usually caused by Gram-positive bacteria (*S. aureus*, *S. epidermidis*, *S. pneumoniae*, and *S. viridans*). Gram-negative organisms that have been implicated include *Haemophilus* species, *E. coli*, *Proteus* species, *K. pneumoniae*, *Enterobacter* species, and *Serratia marcescens*.<sup>48</sup> Rarely, *pseudomonas* sp. causes corneal ulceration and perforation.<sup>49</sup>

Typically, these infections arise 2–5 days after birth. Signs include lid edema, chemosis, and conjunctival injection with discharge. The work-up includes conjunctival scrapings for Gram staining and cultures, the results of which direct the choice of therapy. For Gram-positive organisms, erythromycin 0.5% ointment four times a day is administered. Gentamicin, tobramycin, or fluoroquinolone drops or ointment four times a day can be used for Gram-negative organisms (see Table 4.6.3).

### Viral Infections

Viral conjunctivitis of the newborn is rare but can be associated with significant morbidity and mortality. Both herpes simplex virus type 1 and herpes simplex type 2 can be associated with conjunctivitis, but type 2 infection is more common.<sup>50</sup> Type 1 may be transmitted by a kiss from an adult who has an active “cold sore,” and type 2 is more commonly transmitted through the birth canal. Onset is usually within the first 2 weeks of life

and may be associated with vesicular skin lesions of the lid or lid margin (see Fig. 4.6.8). The conjunctivitis may be followed by herpetic keratitis or keratouveitis. Vitritis, retinitis, retinal detachment, optic neuritis, and cataract all have been reported in association with neonatal ocular herpes. The diagnosis may be confirmed by the presence of eosinophilic intranuclear inclusions on smears, positive viral culture results, or positive results from monoclonal antibody immunoassays.

Treatment consists of trifluoridine 1% drops every 2 hours for 7 days, acyclovir ointment five times a day, or ganciclovir drops five times a day (see Table 4.6.3). Herpes simplex type 2 may be more resistant to treatment. In cases of systemic disease associated with pneumonitis, septicemia, and meningitis, systemic acyclovir or valacyclovir should be used. Good prenatal care and frequent culture and treatment of mothers who have known herpes genital infections decrease the incidence of herpetic neonatal conjunctivitis.

## Fungal and Parasitic Conjunctivitis

Focal eyelid or conjunctival granulomas can be caused by rare infections, including blastomycosis, sporotrichosis, rhinosporidiosis, cryptococcosis, leishmaniasis, and ophthalmomyiasis.

## Microsporidial Keratoconjunctivitis

Microsporidae are obligate, intracellular, spore-forming protozoan parasites that can cause disseminated disease or localized keratoconjunctivitis.<sup>51</sup> It is more commonly seen in immunocompromised patients but has been reported in immunocompetent patients with contact lens use, trauma, prior refractive surgery, or exposure to contaminated water or soil.<sup>52</sup> Clinical symptoms include pain, redness, and, occasionally, visual blurring. Superficial, multifocal, coarse, punctate epithelial keratitis, and a diffuse papillary conjunctivitis are typical.<sup>53</sup> Diagnosis is made with ocular surface scraping and the visualization of acid-fast spores in conjunctival epithelial cells upon staining with modified trichrome, potassium hydroxide plus calcofluor white, or Gram stain.<sup>52,53</sup> Confocal microscopy demonstrates spores that are hyperreflective dots. Electron microscopy is the gold standard for diagnosis. Treatment includes topical fumagillin and oral albendazole or itraconazole.<sup>52</sup> Topical fluoroquinolones are effective as monotherapy.<sup>54</sup>

## Loiasis

*Loa loa* is a filarial nematode that is transmitted from human to human by the bite of an infected female deer fly (genus *Chrysops*) that is indigenous to West and Central Africa. The adult worm can migrate subcutaneously from the bite area to the eye. Skin manifestations and conjunctivitis can be present. Extraction of the filarial worm is curative. Treatment consists of diethylcarbamazine 2 mg/kg three times daily for 3 weeks.<sup>55</sup> Ivermectin 150 mg/kg can be used, but significant side effects include subconjunctival and retinal hemorrhages and retinal “cottonwool” spots.<sup>56</sup> Concurrent corticosteroids and/or antihistamines can be used to decrease the side effects of treatment.

## Parinaud’s Oculoglandular Syndrome

Parinaud’s oculoglandular syndrome is an uncommon granulomatous conjunctivitis seen in approximately 5%–10% of patients with systemic infection caused by *Bartonella henselae* (cat scratch disease).<sup>57</sup> *B. henselae* are small, fastidious Gram-negative rods that affect approximately 22 000 patients in the United States per year.<sup>58</sup> Ocular symptoms include unilateral redness, epiphora, foreign body sensation, and mild lid swelling. Serous discharge may be present; if an abscess forms and ruptures, purulent discharge may be noted. Granulomatous nodules develop on the palpebral and bulbar conjunctiva approximately 3 days after inoculation (Fig. 4.6.11). Necrosis and ulceration of the overlying epithelium is common.<sup>59</sup> Firm and tender regional lymphadenopathy of the preauricular, submandibular, and, occasionally, cervical nodes are a hallmark of the disease (Fig. 4.6.12). Optic neuroretinitis and multifocal chorioretinitis may develop. Diagnosis can be made by indirect immunofluorescence antibody testing or by enzyme immunoassay. Serological testing includes cultures and PCR.

The course of the disease in immunocompetent patients is usually self-limiting, and the disease resolves without antibiotic therapy. Therapy is recommended for immunocompromised patients. Currently recommended therapies include oral erythromycin, doxycycline, or azithromycin. In adults, doxycycline 100 mg twice daily is thought to be more effective

**Fig. 4.6.11 Parinaud’s Oculoglandular Syndrome.** Granulomatous palpebral conjunctivitis.

**Fig. 4.6.12 Parinaud’s Oculoglandular Syndrome.** Prominent preauricular lymphadenopathy.

**Fig. 4.6.13 Molluscum Contagiosum Lesion on the Lower Eyelid.** This patient had an accompanying chronic follicular conjunctivitis secondary to the toxic effect of viral proteins from this lesion.

because of its superior intraocular and central nervous system penetration. In more severe infections, these medications can be given intravenously, and rifampin can be used as an adjuvant.<sup>59</sup>

## NONINFECTIOUS CONJUNCTIVITIS

### Toxic Follicular Conjunctivitis

Toxic follicular conjunctivitis follows chronic exposure of the conjunctiva to a variety of foreign substances, including molluscum contagiosum of the lid margin, infection of the lashes by *Phthirus pubis*, use of eye cosmetics, and prolonged use of eye medications. Molluscum contagiosum infections are caused by a poxvirus and are common in patients with HIV infection. The infection is characterized by elevated, round, pearly white, waxy, noninflammatory lesions with umbilicated centers (Fig. 4.6.13). When these lesions occur on or near the eyelid margin, the viral proteins

### BOX 4.6.2 Ocular Medications That Cause Toxic Follicular Conjunctivitis

- Neomycin
- Idoxuridine
- Gentamicin
- Trifluorothymidine
- Dipivefrin
- Pilocarpine
- Apraclonidine
- Eserine
- Atropine
- Epinephrine (adrenaline)
- Preservatives (thimerosal, benzalkonium chloride)

spill onto the conjunctiva to cause a chronic follicular conjunctivitis.<sup>60</sup> The virus itself does not grow in the conjunctiva; rather, the conjunctivitis is a toxic reaction to its proteins. Removal of the lesion or curettage until it bleeds internally eliminates this condition.

Most commonly, toxic follicular conjunctivitis occurs in association with eye medications, such as neomycin, gentamicin, idoxuridine, and other topical antivirals, as well as many glaucoma medications, including brimonidine, pilocarpine, and other miotics (Box 4.6.2). These drugs incite type IV delayed hypersensitivity reaction with periocular erythema and follicular conjunctivitis. In contact lens wearers, any proteolytic enzymes/chemicals used for contact lens cleaning or preservative-containing soaking solutions can cause toxic conjunctivitis. A marked follicular response also can accompany the use of eye cosmetics, such as mascara and eyeliner. A common finding is dark granules from the cosmetic incorporated in the follicles. If symptomatic, patients usually respond well to discontinuation of the cosmetic and substitution of smaller amounts of hypoallergenic preparations.

### Erythema Multiforme Major (Stevens–Johnson Syndrome) and Toxic Epidermal Necrolysis

Erythema multiforme, unlike cicatricial pemphigoid, is an acute, generally self-limiting, nonprogressive inflammatory disorder of the skin and mucous membranes; it is classified into minor and major forms. The minor form primarily involves the skin and lasts 2–3 weeks in its acute phase. Erythema multiforme major, also known as *Stevens–Johnson syndrome*, is the more serious variant, characterized by skin lesions and erosive involvement of mucous membranes that lasts up to 6 weeks.<sup>61</sup> Toxic epidermal necrolysis is a severe variant of erythema multiforme major that is characterized by massive denudation of the epidermis and is more commonly seen in children and in patients with AIDS.<sup>62</sup> Erythema multiforme major classically occurs in previously healthy young people, men more than women, in their first 3 decades of life.<sup>61</sup> A genetic predisposition may exist for the development of Stevens–Johnson syndrome with ocular involvement, in association with human leukocyte antigens HLA-Bw44 and HLA-B12.<sup>63</sup> The disease can be fatal in 2%–25% of patients, with death often secondary to sepsis. About 25% of those who have erythema multiforme suffer a recurrence over their lifetime.

The exact cause of erythema multiforme is unknown, although the disease seems to be precipitated by numerous antigens, including bacteria (e.g., *Mycoplasma pneumoniae*), viruses, fungi, and drugs. Herpes simplex virus and *Mycoplasma* have a particularly strong association. Coxsackievirus and *Histoplasma capsulatum* also have been implicated.<sup>64</sup> Drugs implicated in the development of erythema multiforme include the sulfonamides, penicillins, barbiturates, nonsteroidal anti-inflammatory medications, salicylates, mercurial agents, arsenic, allopurinol, phenylbutazone, phenytoin, and topical ophthalmic scopolamine (hyoscine), tropicamide, and proparacaine.<sup>65</sup> In addition, the onset of the disease has been related to neoplasms, radiation therapy, collagen vascular diseases, and vaccinations.<sup>62</sup>

Erythema multiforme often begins with a prodromal period for up to 2 weeks with symptoms of malaise, fever, headache, and an upper respiratory tract infection. Next, skin lesions develop symmetrically on the extremities with sparing of the trunk and can reoccur for 2–6 weeks before re-epithelization (Fig. 4.6.14). The primary cutaneous lesion is a round, erythematous macule that develops into a papule and then a vesicle or bulla. Eventually, large bullae can rupture, which results in epidermal necrosis.

**Fig. 4.6.14 Acute Phase of Stevens–Johnson Syndrome.** This child has the typical target-shaped macular skin lesions. (A) The head, with an associated blepharoconjunctivitis. (B) The leg.

If extensive skin necrosis occurs, the condition is labeled *toxic epidermal necrolysis* (Fig. 4.6.15). The extent of mucous membrane involvement usually parallels the extent of skin involvement. Any mucous membrane may be involved, but the mouth and eyes are affected most frequently and most severely. In one study, 100% of patients had stomatitis and 63% had conjunctivitis.<sup>66</sup> The diagnosis is confirmed by skin or mucosal biopsy demonstrating multiple necrotic keratinocytes or full-thickness epidermal necrosis with subepidermal blistering.<sup>64</sup>

The acute phase of ocular involvement lasts 2–3 weeks.<sup>67</sup> The lids become swollen, ulcerated, and crusted. Patients develop an acute bilateral conjunctivitis, with chemosis, vesicles and bullae, pseudo-membranes or membranes, and eventual ulceration. A more purulent conjunctivitis may develop as a result of bacterial secondary infection.<sup>65</sup> The major ocular problems occur from the cicatricial stage, after the acute toxic episode subsides. Conjunctival scarring and symblepharon may occur despite all supportive measures (Fig. 4.6.16). Destruction of the conjunctival goblet cells, lacrimal gland, and accessory lacrimal gland tissue results in a severe dry

**Fig. 4.6.15 Severe Skin and Conjunctival Necrosis.** The patient has toxic epidermal necrolysis.

**Fig. 4.6.16 Stevens–Johnson Syndrome.** Residual conjunctival scarring is evident over the superior tarsal plate. Symblepharon formation and fibrous bands are present at the canthal angles.

eye, just as in cicatricial pemphigoid. Entropion, trichiasis, and lagophthalmos combined with the dry eye can produce severe corneal problems, such as ulceration, vascularization, opacification, limbal stem cell deficiency, and eventual perforation.<sup>67</sup> Although the acute phase of erythema multiforme may leave extensive conjunctival scarring in its wake, progressive scarring does not occur when the acute disease has subsided, unlike cicatricial pemphigoid. Fortunately, recurrences rarely involve the conjunctiva.

The histological changes in erythema multiforme suggest an underlying vasculitis or perivasculitis.<sup>61</sup> Mononuclear cells, eosinophils, and polymorphonuclear neutrophils accumulate around the vessels or within the vessel wall and induce fibrinoid necrosis of the wall. Subepithelial bullae are seen in the acute phase, and pseudo-membranes and true membranes are found. Conjunctival goblet cell densities are reduced. Immunoglobulins and complement are also deposited at the dermal–epidermal junction.

Treatment often varies with the severity of the condition. Patients who have a more severe initial presentation suffer the worst late ocular complications. In the acute phase, local treatment involves lubrication of the ocular surface. Frequent lysis of developing symblepharon may have no effect on the eventual structure. Unfortunately, local medical treatment of the acute condition often has little influence on the severity of the eventual cicatricial complications. However, systemic corticosteroids (prednisone 60–80 mg/day for 3–4 weeks) may help control the acute disease.<sup>68</sup> Plasmapheresis, systemic cyclosporine, and intravenous immunoglobulins have had variable results and remain controversial.<sup>64</sup> Secondary bacterial conjunctivitis should be suspected and treated, if present; an antibiotic that could, however, stimulate another toxic reaction should be avoided. The cicatricial stage is treated with frequent nonpreserved artificial tears and/or ointments, topical cyclosporine, autologous serum tears, punctal occlusion, and tarsorrhaphy to control dry eye symptoms and prevent sequelae. Surgery to correct lid keratinization, entropion, and trichiasis should be

considered. Unlike in cicatricial pemphigoid, eyelid or conjunctival surgery does not stimulate further scarring. Conjunctival or buccal mucous membrane grafts may be considered to restore the ocular surface. Transplantation of cryopreserved amniotic membrane grafts within the first 2 weeks of the onset of symptoms has been shown in numerous case reports to facilitate rapid epithelial healing and prevent many of the debilitating cicatricial complications.<sup>69</sup> Stem cell transplantation through the use of living-related or cadaveric conjunctival and limbal allografts is often done with subsequent penetrating keratoplasty or keratoprosthesis in patients with severe corneal complications.

## Epidermolysis Bullosa

Epidermolysis bullosa comprises a group of skin and mucous membrane diseases that are characterized by the tendency to form blisters after minor trauma.<sup>70</sup> Symptoms occur shortly after birth or in early childhood and have a tendency to recur throughout the patient's life. Men and women are affected equally, and both hereditary and acquired autoimmune forms exist.<sup>71</sup> The hereditary forms of epidermolysis bullosa may be classified as simple (autosomal dominant), junctional (autosomal recessive), and dystrophic (autosomal dominant or recessive).

Ocular problems have been described with all three types; they are, however, associated mostly with the dystrophic form, which is the most common form of the disease. Patients may have conjunctival blisters and marked conjunctival scarring, with symblepharon formation and eyelid ectropion or entropion.<sup>72</sup> A granular epithelial clouding of the cornea can occur, as can ulcers and opacification secondary to conjunctival scarring similar to that seen in cicatricial pemphigoid or erythema multiforme. Patients who have the junctional form, a rare type, have more primary corneal problems, such as recurrent erosions, and little conjunctival involvement. The acquired, autoimmune form may have both primary corneal subepithelial vesicles and secondary corneal involvement associated with conjunctival scarring and symblepharon.

Treatment is based on the severity of disease. A majority of patients can be treated conservatively with ocular lubricants. Various types of corneal surgery, including keratoplasty, may be indicated if significant scarring and visual loss occurs. Tarsorrhaphy and ectropion/entropion surgery may be considered for patients with more severe disease.<sup>73</sup>

## Graft-versus-Host Disease

Graft-versus-host disease (GVHD) is a common complication of allogeneic bone marrow transplantation and results from donor-grafted cells attacking host tissue antigens. Involved tissues include skin, gastrointestinal tract, lungs, liver, and eyes. Acute or chronic (developing after day 100 following transplantation) disease can occur, but ocular manifestations are more common with chronic GVHD. Ocular complications are secondary to two main mechanisms: conjunctival inflammation in acute disease secondary to T cell–mediated immunity and in chronic disease secondary to infiltration of the lacrimal gland by T lymphocytes causing destruction and fibrosis of the lacrimal gland and conjunctiva. Both pathways lead to keratoconjunctivitis sicca. Signs and symptoms include aqueous tear deficiency, conjunctival erosions, corneal epithelial erosions, and cicatricial lagophthalmos.<sup>73</sup> Histologically, the conjunctiva in GVHD is characterized by decreased conjunctival goblet cell density, increased squamous metaplasia, and infiltration of inflammatory cells.<sup>74</sup> Therapy consists mainly of aggressive lubrication, autologous serum tears, punctal plugs, and decreasing ocular inflammation with topical corticosteroids and/or topical cyclosporine or tacrolimus. Bandage contact lenses and fluid ventilated gas permeable sclera lenses also provide symptomatic relief. Mucolytic agents, such as 10% acetylcysteine, can be used to treat severe filamentary keratitis. Severe ocular disease accompanied by systemic complications warrants increased systemic immunosuppression. Malta et al. suggested that treatment with topical cyclosporine 1 month prior to bone marrow transplantation could help delay or prevent lacrimal gland damage and decrease the ocular symptoms of early GVHD.<sup>75</sup>

## Xeroderma Pigmentosa

Xeroderma pigmentosa is an autosomal recessive disease characterized by impaired ability to repair damage to DNA caused by ultraviolet radiation. Ocular manifestations include keratoconjunctivitis sicca, photophobia, tearing, blepharospasm, and burning. Conjunctival inflammation, telangiectasia, and hyperpigmentation are common findings. Patients often develop pingueculae or pterygia. The patient's impaired ability to

repair DNA leads to cutaneous neoplasms, including squamous cell carcinoma, basal cell carcinoma, and melanoma, in that order of frequency. Neoplasms of the ocular surface and eyelids occur in approximately 11% of patients and often are seen at the limbus. Progressive atrophy of the eyelids with madarosis, trichiasis, symblepharon, ectropion, and entropion can also occur.

## Kawasaki Disease

Kawasaki disease is a rare self-limiting vasculitis of childhood that presents with a host of symptoms, including fever, bilateral nonexudative conjunctivitis, diffuse rash involving the extremities, cervical lymphadenopathy, and erythema of the oral mucosa. Iridocyclitis is another common finding. There are no sequelae from the ocular symptoms, but prompt recognition and appropriate referral for treatment is important to decrease heart complications secondary to vasculitis.<sup>76</sup>

## Ligneous Conjunctivitis

Ligneous conjunctivitis is a very rare chronic disease characterized by development of pseudo-membranes predominantly on the palpebral conjunctiva. The thick pseudo-membranes evolve into “woody” lesions. Corneal involvement is noted occasionally, and it may lead to scarring and blindness. Some may develop pseudo-membranes over mucosal tissue elsewhere in the body. The disease predominantly is described in children but has been reported in both young and old. The etiology is unclear, but type I plasminogen deficiency is thought to be a predisposing factor for the disease. Management is difficult with frequent recurrences following excision. Topical plasminogen and fibrinolytic therapy has been tried with some success.<sup>77</sup>

# Allergic Conjunctivitis

Jonathan B. Rubenstein, Tatyana Spektor

# 4.7

**Definition:** Allergic conjunctivitis is inflammation of the conjunctiva due to an immediate hypersensitivity reaction to environmental allergens.

## Key Features

- Itching and redness are common presenting symptoms.
- Treatment includes mast-cell stabilizers, antihistamines, combination medications, cool compresses, corticosteroids, and allergen avoidance.

## ACUTE ALLERGIC CONJUNCTIVITIS: SEASONAL/PERENNIAL

Acute allergic conjunctivitis is a type I immediate hypersensitivity reaction mediated by immunoglobulin E (IgE) and subsequent mast-cell activation,<sup>1</sup> stimulated by direct exposure to environmental allergens. The reaction may be limited to the eye, or it may be part of a generalized allergic reaction with nasal and respiratory symptoms. Often a family history of atopy is present. Cytological examination of conjunctival scrapings shows eosinophilic infiltration. Elevated levels of IgE and histamine are found in the tear film.<sup>2</sup> Acute allergic conjunctivitis is divided into seasonal allergic conjunctivitis (SAC) and perennial allergic conjunctivitis (PAC).<sup>3</sup> The onset of symptoms for SAC is seasonally related to circulating aeroantigens. PAC is considered a variant of SAC that persists throughout the year, although seasonal exacerbations often are seen.<sup>2</sup> Clinical symptoms and signs are typically bilateral and consist of itching, burning, and mild to moderate injection that can progress to various degrees of chemosis with superior tarsal conjunctiva papillary reaction. A watery or mucoid “stringy” discharge may be seen.<sup>4</sup>

## CHRONIC ATOPIC KERATOCONJUNCTIVITIS

Chronic atopic keratoconjunctivitis (AKC) is an inflammatory disease that can lead to disabling symptoms involving both the conjunctiva and the cornea. It can present between the late teens through the fifth decade and has a slight male predilection. A large majority of patients have concomitant eczema or asthma.<sup>1</sup> Between 20% and 40% of patients with atopic dermatitis also have AKC.<sup>5</sup> Clinical symptoms include intense bilateral itching, tearing, burning, photophobia, blurred vision, and a stringy mucus discharge. Periorbital eczema, lid edema, conjunctival chemosis, and allergic shiners are common findings. Papillary hypertrophy of the upper tarsal conjunctiva is the most common sign (Fig. 4.71). Cobblestone papillae on the superior tarsal conjunctiva also may occur. Gelatinous limbal hyperplasia and nodules may be present with or without Horner–Trantas dots (areas of eosinophils and degenerating cellular debris). In severe cases, cicatrizing conjunctivitis with subepithelial fibrosis, symblepharon formation, and forniceal shortening may develop.<sup>2</sup> Histopathologically, a mixture of mast cells, eosinophils, and lymphocytes are found in the conjunctival epithelium.

## VERNAL CONJUNCTIVITIS

Vernal conjunctivitis is a bilateral, recurrent inflammation of the conjunctiva that tends to occur in children and young adults with a history of atopy. Its onset is most common in the spring and summer months, and the inflammation often goes into remission during the cooler months.<sup>6</sup> The highest incidence is in the warm, temperate Middle East–Mediterranean region and Mexico. Boys are affected twice as often as girls, with a peak

**Fig. 4.71 Chronic Atopic Conjunctivitis.** Mild conjunctival injection with numerous giant cobblestone papillae.

**Fig. 4.72 Vernal Conjunctivitis.** Cobblestone papillae cover the superior tarsal conjunctiva.

incidence between ages 11 and 13 years. Recent studies have found an association between low serum vitamin D levels in children with vernal conjunctivitis.<sup>7</sup> The prominent symptom is intense pruritus. Other complaints include photophobia, burning, tearing, mild ptosis, and a thick, ropy, yellow, mucoid discharge. It is classically thought to be an IgE-mediated type I hypersensitivity reaction; however, studies have also noted T helper 2 lymphocyte involvement in a type IV immune reaction.<sup>2</sup>

The three forms of the vernal conjunctivitis are palpebral, limbal, and mixed.<sup>8</sup> The palpebral form is marked by cobblestone papillae on the superior tarsal conjunctiva (Fig. 4.72) with minimal involvement of the lower lid. After initial papillary hypertrophy, the connective tissue of the substantia propria undergoes hyperplasia and proliferation to form giant papillae. The pressure of the cornea flattens the tops of the giant papillae to produce a cobblestone pattern. Tiny twigs of vessels are found in the centers of the papillae, which help differentiate these from the large follicles without the

**TABLE 4.7.1 Medications Used in the Treatment of Allergic Conjunctivitis**

Category	Examples	Comments
Histamine 1 (H <sub>1</sub> ) receptor agonists	Levocabastine, emedastine difumarate	Use for isolated, acute allergic attacks. Use alone or in combination with mast-cell stabilizers and nonsteroidal anti-inflammatory drugs (NSAIDs).
Mast-cell stabilizers	Cromolyn sodium, lodoxamide, pemirolast, nedocromil sodium	Most useful for chronic allergies. May take 1–2 weeks to be effective. Pemirolast and nedocromil have antihistamine effects as well. Nedocromil also reduces eosinophil and neutrophil chemotaxis.
Antihistamines with mast cell–stabilizing activity	Olopatadine, alcaftadine, bepotastine, ketotifen fumarate, azelastine, epinastine, bepotastine	These medications combine the immediate effect of selective antihistamines with the long-term effects of mast-cell stabilization. They have convenient once- or twice-a-day dosing. Ketotifen and azelastine have anti-inflammatory properties as well.
Topical NSAIDs	Ketorolac, nepafenac, bromfenac	Can reduce itching, but stings when applied.
Vasoconstrictors	Naphazoline/pheniramine, naphazoline/antazoline	Available over the counter; instruction must be given to avoid chronic use because of the risk of rebound redness; relieves redness, but not other symptoms.
Topical corticosteroids	Loteprednol, fluorometholone, rimexolone	May be useful in serious cases or until control is achieved with other agents. Side-effects limit chronic use.
Oral antihistamines	Fexofenadine, loratadine, cetirizine, ebastine, mizolastine, desloratadine	Useful when systemic allergic symptoms are present but may cause dry eyes.
Immunomodulators	Tacrolimus, cyclosporine	Useful in refractory cases or situations where corticosteroid use is not appropriate.

central vessels seen in trachoma. The limbal form is marked by a broad, thickened, gelatinous opacification of the superior limbus that can override the cornea (Fig. 4.7.3). Tiny, twig-like vessels arise in the centers of these rounded lumps, as opposed to limbal follicles, where the vessels appear around the sides of the elevations. Histologically, the tissue is infiltrated with lymphocytes, plasma cells, macrophages, basophils, many eosinophils, and an increased number of conjunctival goblet cells (Fig. 4.7.4). Horner–Trantas dots, which are white, chalk-like gelatinous nodules composed of eosinophils and epithelial debris located at the limbus, are characteristic in limbal vernal keratoconjunctivitis (VKC). Patients with VKC also have elevated levels of histamine with other cytokines and immunological molecules in the tear film.

The cornea is involved in about half the cases. Corneal manifestations include a superficial pannus and a punctate epithelial keratitis. Small, gray patches of necrotizing epithelium may involve the upper one third to two thirds of the cornea—in severe cases, the cornea appears to be dusted with flour.<sup>8</sup> The affected area stains with fluorescein. A vernal “shield ulcer” develops as a horizontal oval, shallow, nonvascularized, indolent ulcer of the superior cornea (see Fig. 4.7.4) that leads to severe discomfort. The edges are composed of shaggy, gray, dead epithelial cells, and infiltration of the underlying superficial stroma is present. After the ulcer heals, a mild corneal opacity may persist at the level of Bowman’s layer.

## TREATMENT OF ALLERGIC/ATOPIC KERATOCONJUNCTIVITIS

Treatment of all of the above conditions is based on the severity and chronicity of the disease in each patient. For all cases, cold compresses,

preservative-free artificial tears (refrigerated), and avoidance of allergens can help alleviate symptoms. Unfortunately, avoidance of the offending antigens is often difficult, thus medications are used for further symptomatic control (Table 4.7.1).

Treatment regimens include topical decongestants, antihistamines, mast cell–stabilizing agents, and anti-inflammatory agents. Topical decongestants, which act as vasoconstrictors, can be used symptomatically with mild allergic reactions to alleviate erythema and tearing. However, chronic use can lead to rebound hyperemia that limits their efficacy. Histamine (H<sub>1</sub> receptor–specific) antagonists (see Table 4.7.1) can be used for intermittent, acute allergic reactions from a limited exposure to the antigen. Mast-cell stabilizers (see Table 4.7.1) are used as long-term maintenance therapy for chronic allergies.<sup>9</sup> They act by reducing intracellular, calcium-dependent secretory events and decreasing synthesis/secretion of leukotrienes, chemokines, and other proinflammatory mediators.<sup>10</sup> Combination medications that act as both mast-cell stabilizers and H<sub>1</sub>-specific antagonists (see Table 4.7.1) have become a mainstay of treatment.<sup>3,10</sup>

Preseasonal treatment with a combination medication has been shown to suppress clinical symptoms in patients with SAC.<sup>11</sup> Noncorticosteroidal anti-inflammatory agents and topical corticosteroids can be used to reduce the acute inflammatory response in severe cases until the mast-cell stabilizers and antihistamines take effect. Corticosteroids are then tapered off as the therapeutic effects of the maintenance medications take hold. Topical cyclosporine 0.5%–2% has also been effective in the treatment of VKC, atopy, and other forms of severe allergic disease.<sup>12</sup> Topical tacrolimus ointment, which is known to inhibit T-lymphocyte activation, has been used to treat corticosteroid-resistant or unresponsive AKC, VKC, and severe cases of GPC.<sup>5,13</sup> Evaluation by an allergist is recommended in severe cases.

**Fig. 4.7.5 Allergic Dermatoconjunctivitis.** Contact allergy of the eyelids after exposure to neomycin eyedrops. The skin shows a typical eczematous dermatitis.

## ALLERGIC DERMATOCONJUNCTIVITIS

Contact allergy of the eyelids and conjunctiva represents the most common form of allergic reaction seen by the ophthalmologist. It represents a delayed, cell-mediated (type IV) hypersensitivity reaction. In patients with previous sensitization, the immune reaction can take 48–72 hours to develop. Common stimuli include eyedrops (neomycin, gentamicin, idoxuridine, atropine, thimerosal, and penicillin<sup>13</sup>), cosmetics, clothing, jewelry, plastics, animal or vegetable products, and industrial chemicals.<sup>14</sup> The reaction usually begins with severe itching and a papillary conjunctivitis that is worse on the inferior palpebral conjunctiva. A mucoid or mucopurulent discharge is seen. The adjacent skin of the lower lids and lateral canthi becomes involved in a typical eczematous dermatitis (Fig. 4.7.5). Chronic exposure can lead to keratinization of the lid with punctal edema and stenosis. The cornea may show punctate epithelial keratitis and erosions. Conjunctival scrapings show monocytes, polymorphonuclear neutrophil leukocytes, mucus, and eosinophils. Treatment includes eliminating the antigenic stimulus and quieting the eye with antihistamines, mast-cell stabilizers, and topical corticosteroids.

## MICROBIAL ALLERGIC CONJUNCTIVITIS

Microbial allergic conjunctivitis is a type IV hypersensitivity response to the toxic protein breakdown products of bacterial disintegration, most commonly from chronic staphylococcal blepharoconjunctivitis. The formation of bacterial breakdown products causes an allergic response in the conjunctiva and cornea.<sup>15</sup> Typically, patients do not have a history of atopy. Marginal infiltrates of the cornea can be associated with this condition (Fig. 4.7.6).<sup>14</sup>

Phlyctenular keratoconjunctivitis is another manifestation of microbial allergic conjunctivitis. In the past, it was commonly associated with tuberculosis. Today, it is most frequently seen with chronic staphylococcal blepharoconjunctivitis. Other possible sources include *Candida albicans*, *Coccidioides immitis*, *Chlamydia*, parasites, and lymphogranuloma venereum. Phlyctenular disease presents as slightly raised, small, pinkish white or yellow nodules surrounded by dilated vessels located on conjunctiva near the limbus or into peripheral cornea. After a few days, the center of the lesion then ulcerates, sloughs, and clears without scarring. Classically, there is no clear zone between the limbus and the lesion. Involvement is usually bilateral and seasonal (occurring more in spring and summer), and the condition occurs most frequently in children and young adults.

Treatment includes identifying the inciting organism and eradicating it. Twice-daily lid scrubs (mechanical debridement of the lid margins with dilute baby shampoo or commercially prepared lid scrub pads) can usually achieve symptomatic improvement. Topical antibiotic or antibiotic-corticosteroid combination ointments or drops rubbed into the lid margins may reduce the number of bacterial colonies. Corticosteroids are reserved for chronic recalcitrant blepharoconjunctivitis and are beneficial early in the treatment of phlyctenular disease. Tuberculosis should be ruled out, when appropriate. Systemic antibiotics, such as oral tetracycline 250 mg four times a day or oral doxycycline 100 mg twice a day, can help in

**Fig. 4.7.6 Microbial Allergic Keratoconjunctivitis Associated With Staphylococci.** A staphylococcal marginal infiltrate is seen in the superior cornea.

**Fig. 4.7.7 Giant Papillary Conjunctivitis.** Giant papillae cover this patient's superior tarsal conjunctiva after chronic exposure to soft contact lenses.

cases of nontuberculous phlyctenular disease or persistent staphylococcal blepharoconjunctivitis.

## GIANT PAPILLARY CONJUNCTIVITIS

Giant papillary conjunctivitis (GPC) is a syndrome of inflammation of the upper palpebral conjunctiva associated with contact lens wear, ocular prostheses, and protruding ocular sutures.<sup>16,17</sup> It is primarily linked to contact lens wear and is seen 10 times more frequently in soft lens wearers than in rigid lens wearers.<sup>17</sup> The average time for the development of symptoms is 8 months for soft lens wearers and 8 years for hard lens wearers. Estimates of the prevalence vary from 1% to 5% of soft lens users to 1% of rigid lens users.

Patients complain of mild itching after removal of the contact lenses and increased mucus on the lenses and in the nasal canthus upon awaking. They also complain of increased lens awareness, blurring of vision after hours of lens wear, excessive lens movement, and eventual contact lens intolerance. Signs initially include a generalized thickening and hyperemia of the superior pretarsal conjunctiva. The normally small papillae become elevated. The conjunctiva becomes more translucent and eventually becomes opaque secondary to cellular infiltration. Macropapillae (0.3–1.0 mm) and giant papillae (1.0–2.0 mm) then form (Fig. 4.7.7). Trantas dots and gelatinous nodules may develop at the limbus.<sup>18</sup> Inspection of the contact lenses almost always reveals whitish protein deposits.

The histology of GPC shows irregular thickening of the conjunctival epithelium over the papillae, with epithelial downgrowth into the stroma. The epithelium and stroma show infiltration of lymphocytes, plasma cells, polymorphonuclear neutrophil leukocytes, eosinophils, basophils, and macrophages along with fibroblast proliferation. The number of eosinophils and basophils is considerably lower than that seen in vernal conjunctivitis.

The cause of GPC is multifactorial. Patients likely have environmental antigens that adhere to the mucus and proteins that normally coat the surface of all contact lenses.<sup>19</sup> These antigens, which persist as deposits on the contact lenses, are forced into repeated contact with the superior tarsal conjunctiva with blinking. Mechanical trauma also is an important factor in the pathogenesis of GPC and develops in patients who have ocular prostheses and exposed suture ends. The repeated mechanical trauma induces expression of interleukin-8 with recruitment of dendritic cells that increases the number of antigen-presenting cells.<sup>5</sup> Repeated exposure to antigens combined with the trauma from contact lens wear may stimulate a type IV basophil hypersensitivity of the conjunctiva. A type I IgE-mediated immediate hypersensitivity reaction occurs as well.

Treatment of the condition requires removal of the inciting factor. Loose sutures should be removed, and ocular prostheses may need to be refitted. In contact lens wearers, initial discontinuation of lens wear is necessary until the inflammation subsides, which can take months. Lens wear may resume once symptoms improve, but decreasing daily wear time and good lens hygiene are essential. Patients must be instructed to clean their contacts thoroughly each night, and an attempt should be made to remove preservatives from the lens care system. Disinfection with a hydrogen peroxide system and regular enzymatic treatment help decrease buildup on the lenses. Often switching to a different lens polymer allows more than 80% of patients to continue contact lens wear.<sup>20</sup> Daily disposable soft contact lenses should be encouraged and often are well tolerated. If soft lenses do not work, a rigid gas-permeable lens can be tried. In the early stages of GPC a combination drop of antihistamine and mast-cell stabilizer can be effective in the resolution of some symptoms. Maintenance therapy with combination drops is typically necessary to prevent recurrence. A short course of topical corticosteroids or corticosteroid-sparing medications, such as cyclosporine or tacrolimus, can lessen the symptoms in severe cases.

# Tumors of the Conjunctiva

James J. Augsburger, Zélia M. Corrêa, Bitá Esmaeli

## 4.8

**Definition:** Spectrum of malignant and benign neoplasms, choristomas, and hamartomas arising from or occurring within the conjunctiva, and nonneoplastic epibulbar tumors frequently misdiagnosed clinically as a conjunctival malignant neoplasm.

### Key Features

- Solid mass or discrete lesion of conjunctiva.
- Wide spectrum of color, texture, and size of tumor and associated features.
- Substantial differences in age at onset and clinical behavior after detection.

## CONJUNCTIVAL MALIGNANT NEOPLASMS

A conjunctival malignant neoplasm is a tumor (three-dimensional mass) composed of cancer cells involving the conjunctival epithelium, the stroma, or both. The lesions mentioned in this section are all malignant neoplasms (cancerous tumors) and neoplasias of the conjunctiva. There are three principal categories of malignant neoplasms and neoplasias of the conjunctiva: (1) ocular surface squamous neoplasms and neoplasias (squamous cell carcinoma and its variants), (2) conjunctival melanoma, and (3) conjunctival lymphoma. Several other uncommon but clinically important conjunctival neoplasms will also be mentioned.

### Ocular Surface Squamous Neoplasia

The term ocular surface squamous neoplasia (OSSN) encompasses a number of related nonmelanocytic cancers that arise within the epithelium of the conjunctiva, cornea, or both. These cancers range from conjunctival and *corneal intraepithelial neoplasia* (CIN) (essentially carcinoma in situ within the ocular surface epithelium) to nodular squamous cell carcinoma and variants thereof, including mucoepidermoid carcinoma.

Conjunctival/corneal intraepithelial neoplasia is a localized or diffuse replacement of normal conjunctival or corneal epithelium by malignant cells derived from the stratified squamous epithelium.<sup>1</sup> CIN becomes evident clinically when it involves the corneal epithelium and produces a translucent whitening or graying of the involved portions of that epithelium (Fig. 4.8.1). The lesion can cause substantial impairment of visual acuity if it involves the central cornea. When malignant epithelial cells involve only a portion of the thickness of the epithelium pathologically, the condition is called conjunctival or corneal *squamous epithelial dysplasia*. When neoplastic epithelial cells replace full-thickness conjunctival epithelium but do not invade the substantia propria, the condition is referred to as *squamous cell carcinoma in situ*. Most ocular tumor specialists advise excision of conjunctival lesions suspected of being ocular surface squamous neoplasms, and surgical scraping of abnormal appearing corneal epithelium suspected of being corneal intraepithelial neoplasia with submission of the excised specimens to pathology to confirm or rule out the clinical diagnosis before initiating therapies such as topical interferon therapy or topical chemotherapy (see “[Management of Conjunctival Tumors Suspected of Being Malignant Neoplasms or Neoplasias](#)” below).

*Squamous cell carcinoma* of the conjunctiva is a malignant neoplasm of the stratified squamous epithelium of the conjunctiva.<sup>2,3</sup> It appears as a hypervascularized epibulbar tumor that is located most frequently at the limbus medially or temporally. Such tumors occur in three principal clinical patterns. The *leukoplakic tumor* (Fig. 4.8.2) is characterized by hard,

**Fig. 4.8.1 Conjunctival and Corneal Intraepithelial Neoplasia (CIN).** The corneal epithelium is thickened and translucent in the medial and superomedial portions of the cornea.

**Fig. 4.8.2 Leukoplakic Squamous Cell Carcinoma of Conjunctiva.** The discrete white hyperkeratotic limbal plaque is associated with prominent conjunctival blood vessels.

white accumulation of abnormally keratinized conjunctival epithelium overlying the tumor proper. The gelatinous tumor (Fig. 4.8.3) appears as a translucent nodule fed and drained by prominent dilated epibulbar blood vessels. The papillary tumor (Fig. 4.8.4) appears as a pink to reddish mass that exhibits prominent vascular loops internally on slit-lamp biomicroscopy. Many larger tumors exhibit more than one or these clinical patterns (Fig. 4.8.5). Some larger tumors also exhibit ulceration or even intracorneal or intraocular invasion that can be determined by slit-lamp biomicroscopy or ultrasound biomicroscopy (UBM). Aggressive and neglected tumors can invade the orbit and extend partially around the eye, a circumstance that may necessitate exenteration of the orbit.

*Mucoepidermoid carcinoma* (Fig. 4.8.6) is a particularly aggressive form of OSSN that has a strong tendency to recur following attempted excision, invade the eye wall, and invade the orbit.<sup>4</sup> It resembles conventional

**Fig. 4.8.3 Papillomatous Squamous Cell Carcinoma of Conjunctiva.** The pink limbal tumor contains multiple fine intralesional corkscrew blood vessels and is associated with dilated afferent and efferent conjunctival blood vessels.

**Fig. 4.8.6 Mucoepidermoid Carcinoma of Conjunctiva.** This tumor resembles a papillary squamous cell carcinoma near the limbus but has a nodular subepithelial portion extending posteriorly.

**Fig. 4.8.4 Gelatinous Squamous Cell Carcinoma of Conjunctiva.** The translucent limbal mass is associated with dilated afferent and efferent conjunctival blood vessels.

**Fig. 4.8.5 Invasive Squamous Cell Carcinoma of Conjunctiva Exhibiting Leukoplakic, Papillary and Gelatinous Components Plus Central Ulceration.** Note blood within the corneal stroma at the pupillary margin of the tumor.

squamous cell carcinoma quite closely clinically and on routine hematoxylin and eosin-stained microslides but can be distinguished by the presence of prominent goblet cells containing mucin (revealed by stains, such as Alcian blue and mucicarmine) and positive immunoreactivity to immunostain CK7. Because of its aggressively invasive behavior, this ocular surface squamous neoplasm ultimately prompts exenteration in many cases.

Squamous cell carcinoma of the conjunctiva and its variants are the most common primary conjunctival malignant neoplasms encountered in clinical practice.<sup>5</sup> The average annual incidence of squamous cell carcinoma of the conjunctiva across all age groups has been estimated to be approximately 17–20 new cases per million persons per year. For a population with an average life expectancy of 70 years, this average annual incidence translates to a cumulative lifetime incidence of approximately 1 case per 700–850 persons. Most tumors of this category are encountered in persons over age 50 years. Risk factors for occurrence include a history of repeated, intense, sunlight exposure; male gender; outdoor occupations; advanced age; cigarette smoking; a history of squamous cell carcinoma of the skin of the head and neck; blond hair and light complexion; xeroderma pigmentosum; acquired immunodeficiency syndrome (AIDS); and conjunctival infection by human papilloma virus (HPV) types 16 and 18.

## Conjunctival Melanoma

*Malignant melanoma of the conjunctiva* is a cancerous neoplasm that arises from melanocytes that are present normally within the basal layers of the conjunctival epithelium.<sup>6,7</sup> This form of cancer ranges from a flat patch of acquired conjunctival and corneal intraepithelial melanocytic intraepithelial neoplasia (conjunctival–corneal melanoma in situ, malignant primary acquired melanosis) to nodular epibulbar tumors. Most conjunctival melanomas are dark brown but some appear partially if not entirely amelanotic. The only reliable way to distinguish an amelanotic conjunctival melanoma from squamous cell carcinoma or other amelanotic malignant neoplasm is by pathological analysis of the excised or biopsied tumor.

*Primary acquired melanosis (PAM)* of the conjunctiva refers to a patch of intraepithelial melanocytic hyperplasia to neoplasia that develops from a previously unaffected region of the conjunctiva in an adult individual (Fig. 4.8.7).<sup>6</sup> Such melanotic conjunctival patches may contain only benign or mildly atypical intraepithelial melanocytes (benign acquired melanosis) or markedly atypical malignant melanoma cells (malignant PAM or PAM with severe atypia). Although larger and more heterogeneously melanotic conjunctival lesions are more likely to contain malignant melanoma cells compared with smaller and more homogeneously melanotic lesions, no reliable clinical way exists to distinguish between benign and malignant PAM. Excision or biopsy of the lesion with pathological analysis of the intraepithelial melanocytes is necessary for its classification as benign PAM versus PAM with severe atypia (intraepithelial melanoma). Nodular conjunctival melanoma frequently develops from patches of malignant PAM. Underlying PAM should be suspected in cases with nodular conjunctival melanoma associated with patchy flat melanotic conjunctiva.

*Nodular conjunctival melanoma* appears as a solid epibulbar tumor fed and drained by prominent conjunctival blood vessels (Fig. 4.8.8). Such a

**Fig. 4.8.7 Primary Acquired Melanosis of Conjunctiva and Cornea.** The lesion is completely flat within the corneal, limbal, and bulbar conjunctival epithelium.

**Fig. 4.8.8 Nodular Melanotic Conjunctival Melanoma at Limbus.** Note dilated conjunctival blood vessels associated with lesion.

**Fig. 4.8.9 Conjunctival Melanoma Associated With Primary Acquired Melanosis of Conjunctiva.** The nodular conjunctival tumor adjacent limbus is almost completely amelanotic.

tumor can arise *de novo* (i.e., from conjunctiva that appeared normal prior to the tumor's development) or from a patch of PAM. As indicated above, most conjunctival melanomas are melanotic (brown); however, some are hypomelanotic or amelanotic (Fig. 4.8.9). The most common location for development of a conjunctival melanoma is at or adjacent to the limbus medially or temporally. Such tumors are less likely to metastasize compared with those that develop in the caruncle or semilunar fold or from the forniceal or palpebral conjunctiva. Conjunctival melanomas that

**Fig. 4.8.10 Malignant Lymphoma of Conjunctiva.** The tumor is a lumpy, pink, ridge-like mass involving inferior bulbar and forniceal conjunctiva.

metastasize tend to involve regional lymph nodes (preauricular, parotid, and submandibular) on the ipsilateral side of the head and neck initially.<sup>8</sup> Because of this, clinical evaluation should include palpation of the head and neck looking for enlarged lymph nodes. If lymph node metastasis is suspected clinically, lymph node mapping and excision should be considered in conjunction with initial treatment of the conjunctival tumor.

## Conjunctival Lymphoma

*Conjunctival lymphoma* is a form of extranodal non-Hodgkin's lymphoma that arises within the conjunctival substantia propria.<sup>9,10</sup> Tumors of this type appear as salmon-colored subepithelial masses (Fig. 4.8.10) that can be unilateral or bilateral and unifocal to multifocal in each affected eye. Pathological analysis of such tumors characteristically shows a monoclonal collection of atypical lymphoid cells that usually are of B-scan lineage. Different histopathological patterns are associated with varying likelihoods of systemic lymphoma ranging from very low (mucosa associated lymphoid tumor [MALT] lymphoma) to reasonably high (diffuse large B-cell lymphoma and mantle cell lymphoma). Because of this, histopathological analysis of a biopsy specimen from such a tumor always is appropriate to assess prognosis and develop a management plan. The most common current treatment for isolated low-grade conjunctival lymphoma is low-dose fractionated external beam radiation therapy with shielding of the cornea and lens.

In addition to these three most common conjunctival malignant neoplasms, readers should be familiar with uncommon conjunctival malignant neoplasms described below.

*Conjunctival Kaposi's sarcoma* is a malignant neoplasm that arises from blood vessels and possibly other tissue elements within the conjunctival stroma.<sup>11,12</sup> It occurs predominantly in individuals with AIDS or other forms of systemic immunosuppression. The tumor characteristically appears as a dark red, frequently hemorrhagic, conjunctival mass (Fig. 4.8.11) that grows rapidly if untreated. Since introduction of therapeutic regimens that control many of the systemic features of human immunodeficiency virus (HIV) infection, such lesions are much less common than they were several decades ago.

*Sebaceous cell carcinoma* (Fig. 4.8.12) is a malignant neoplasm that arises from the meibomian glands in the tarsal conjunctiva or the Zeis glands associated with the cilia at the lid margins.<sup>13,14</sup> It frequently is misdiagnosed as chronic blepharoconjunctivitis and treated as such for weeks to months before the correct diagnosis is suspected and confirmed pathologically. This form of ocular surface cancer has a strong tendency to involve the conjunctival epithelium diffusely (pagetoid spread), a feature that makes it extremely difficult to eradicate surgically. Histopathological analysis of a tumor specimen is the only reliable way to distinguish sebaceous carcinoma from squamous cell carcinoma and its variants.

*Rhabdomyosarcoma* is a malignant neoplasm that may arise from previously normal muscle cells. Primary orbital rhabdomyosarcoma is much more common than primary conjunctival rhabdomyosarcoma.<sup>15</sup> Primary conjunctival rhabdomyosarcoma usually appears as a rapidly enlarging pale pink to tan tumor within the conjunctival substantia propria (Fig. 4.8.13). The tumor usually develops during the first 2 decades of life. Biopsy of the tumor with pathological analysis of the specimen is essential for prompt

**Fig. 4.8.11 Kaposi's Sarcoma of Conjunctiva.** Note the intensely red color of the tumor and presence of associated subconjunctival blood. This patient had underlying acquired immunodeficiency syndrome (AIDS).

**Fig. 4.8.14 Leukemic Tumor of Conjunctiva.** The tumor is a well-defined, reddish-pink, ridge-like mass involving the superior fornix.

**Fig. 4.8.12 Sebaceous Carcinoma of Conjunctiva.** The tumor replaces semilunar fold and caruncle and involves much of the palpebral conjunctiva and lid margin of the lower eyelid.

**Fig. 4.8.15 Conjunctival Nevus.** The tumor is partly melanotic but predominantly tan and associated with moderately prominent conjunctival blood vessels.

**Fig. 4.8.13 Rhabdomyosarcoma of Conjunctiva and Orbit Presenting as Epibulbar Tumor.** The tumor appears as a pink mass arising from the superior fornix.

diagnosis and successful treatment. Treatment usually consists of debulking of the tumor followed by several cycles of systemic chemotherapy and orbital external beam radiation therapy.

*Leukemic conjunctival tumors* of the substantia propria develop in some patients with leukemia.<sup>16,17</sup> Tumors of this type (Fig. 4.8.14) appear similar to conjunctival lymphomas. They are extremely uncommon but can be the

presenting sign of leukemia in some individuals, and the initial manifestation of relapse of some previously treated leukemias.

## BENIGN CONJUNCTIVAL NEOPLASMS AND NEOPLASIAS

A *benign conjunctival neoplasm* is an acquired tumor composed of noncancerous cells and develops within previously normal-appearing conjunctival epithelium, substantia propria, or both. A *conjunctival choristoma* is a congenital tumor of the conjunctiva composed of noncancerous cells that are not normally present within that tissue. A *conjunctival hamartoma* is a congenital tumor of the conjunctiva composed of noncancerous cells that are present normally in that tissue but are present in excessive number and with atypical or disorganized tissue architecture. Although tumors of the latter two types are not precisely “neoplasms,” they are lumped together with benign neoplasms and neoplasias in this section.

### Conjunctival Nevus

The *conjunctival nevus* is a benign neoplasm consisting of mildly atypical but noncancerous melanocytes that arose from normal conjunctival melanocytes within the basal layers of the conjunctival epithelium.<sup>18</sup> This tumor is, by far, the most common primary ocular neoplasm encountered in clinical practice. The typical lesion is not present at birth in most patients but develops later in life (most frequently within the first 2 decades of life) from previously normal appearing conjunctiva, typically at the limbus medially or temporally. The lesion appears as a discrete brown to tan conjunctival tumor in most patients (Fig. 4.8.15) but is completely amelanotic and

**Fig. 4.8.16 Benign Acquired Melanosis of Conjunctiva.** The bulbar conjunctival melanosis is more prominent OS (left eye) than OD (right eye) but was evident along the limbus OU (both eyes) symmetrically in this dark-skinned individual.

**Fig. 4.8.17 Conjunctival and Intrascleral Hemangioma.** This congenital vascular tumor is composed of bright red superficial blood vessels and darker intrascleral blood vessels.

translucent in some persons. The lesion is typically not associated with any prominent dilated tortuous epibulbar feeder and drainer blood vessels. On slit-lamp biomicroscopy, numerous intraepithelial microcysts commonly are evident within such a lesion. Limited slow enlargement and darkening of such lesions is frequently reported by the parents of the affected child. Such lesions appear to have very limited malignant potential.

### Benign Acquired Melanosis of Conjunctiva

Many patients (particularly those of races with dark pigmentation) develop progressive acquired conjunctival melanosis, almost always bilaterally and most frequently in the limbal region (Fig. 4.8.16), as they age.<sup>19</sup> In some patients, the melanosis also involves the bulbar, forniceal, and even palpebral conjunctiva in patchy fashion. This form of acquired conjunctival melanosis is almost always benign histopathologically and rarely gives rise to conjunctival melanoma.

### Conjunctival Hemangioma

A *conjunctival hemangioma* is a benign blood vessel tumor of the conjunctival stroma.<sup>20</sup> In many patients, the lesion is present at birth. In such patients, the lesion should probably be regarded as a hamartoma. Small lesions of this type are usually asymptomatic and can be left alone. In contrast, complex epibulbar hemangiomas (Fig. 4.8.17) can be objectionable cosmetically. Repeated sessions of cryotherapy often are quite effective in reducing the size and decreasing the brightness of such lesions. In the authors' experience, attempts to excise such lesions or treat them with sclerosing solutions usually are unsuccessful and frequently make the situation worse. Fortunately, such tumors have limited if any malignant potential.

### Conjunctival Squamous Papilloma

A *benign squamous papilloma* of the conjunctiva is a neoplasm composed of nonmalignant vascularized fronds of subepithelial connective tissue covered by intact stratified squamous epithelium (Fig. 4.8.18).<sup>21</sup> It may be columnar or sessile in shape. Many lesions of this type that have been evaluated microbiologically have been found to harbor HPV type 6 or 11, and others have been linked to other HPV subtypes.

**Fig. 4.8.18 Squamous Papilloma of Conjunctiva.** The tumor is a pink columnar tumor arising from the peripheral bulbar conjunctiva.

**Fig. 4.8.19 Lymphangioma of Conjunctiva.** The limited bulbar conjunctival tumor consists of dilated lymphatic channels filled with yellow-tinted clear fluid.

### Conjunctival Lymphangioma

A *conjunctival lymphangioma* (Fig. 4.8.19) is an ill-defined tumor of the conjunctival substantia propria composed of mature lymphatic channels in excessive amounts.<sup>22</sup> In most cases, the conjunctival tumor is the anterior and, therefore, visible portion of a more extensive orbital lymphangioma. Such tumors are probably congenital in many cases (in which case they should be categorized as conjunctival hamartomas) but frequently do not show up until late in childhood to early adult years, typically in association with an upper respiratory or sinus infection. The lesion may enlarge abruptly and sometimes fills with blood. Piecemeal excision of the lesion, supplemented by cryotherapy, frequently is performed to treat prominent tumors of this type.

### Conjunctival Choristomas

*Conjunctival choristomas* are benign congenital tumors composed of non-malignant cells and tissues that do not occur normally in the conjunctiva. The cells and tissues that comprise the tumor are generally arranged haphazardly. The tumor frequently contains both mesodermal and ectodermal elements, in which case it is referred to as a *dermoid tumor*. Because many of the conjunctival tumors categorized as choristomas are not detected until late childhood to early adulthood, their congenital nature frequently cannot be verified. Several discrete subtypes of conjunctival choristomas exist, including those discussed below.

### Limbal Dermoid

The *limbal dermoid* is the most frequently encountered type of conjunctival choristoma. This lesion is present at birth and appears as an off-white to fleshy tumor overlying the corneoscleral limbus, most commonly inferotemporally (Fig. 4.8.20).<sup>23</sup> The typical tumor contains both mesodermal elements (most commonly fibroblasts, hair follicles, and fat) and ectodermal

**Fig. 4.8.20 Limbal Dermoid Tumor.** The tumor is an off-white, discoid mass straddling the limbus inferotemporally.

**Fig. 4.8.22 Dermolipoma of Conjunctiva.** This tumor is pale pink with a yellowish tint and soft to palpation.

**Fig. 4.8.21 Solid Dermoid Tumor of Conjunctiva.** The tumor is heterogeneously pigmented and contains several protruding hair shafts.

**Fig. 4.8.23 Conjunctival Osteoma.** This epibulbar tumor is hard but nontender. It is off-white in color and therefore difficult to image well.

elements (epithelial cells). Such lesions are a typical feature of Goldenhar's syndrome and often are bilateral in individuals with this disorder. Excision of the lesion by lamellar or penetrating keratoplasty can be performed if the lesion is objectionable cosmetically, causing induced astigmatism with potential for amblyopia.

### **Conjunctival Solid Dermoid**

The conjunctival solid dermoid is a nodular nonlimbal conjunctival tumor composed of benign mesodermal and ectodermal cells.<sup>24</sup> A tumor of this type is generally heterogeneously pigmented and frequently exhibits prominent hair shafts protruding from its surface (Fig. 4.8.21). Such tumors are commonly not noted until late childhood or early adolescence, and the timing of development of these lesions is unknown. Treatment is simple excision.

### **Conjunctival Dermolipoma**

The *conjunctival dermolipoma* is a soft tissue tumor composed almost exclusively of fat within the substantia propria of the conjunctiva, almost always superotemporally.<sup>25</sup> The tumor appears similar to a prolapsed orbital fat pad that develops in some older adults (Fig. 4.8.22); true conjunctival dermolipomas, however, tend to become apparent much earlier in life.

### **Conjunctival Osteoma**

The *conjunctival osteoma* is a rare benign conjunctival choristoma composed predominantly of bone that develops within the substantia propria, most commonly in the superotemporal fornix region (Fig. 4.8.23).<sup>26</sup> The lesion enlarges slowly and asymptotically and usually is not noted until the teenage years. It generally is found when the affected individual rubs the eye and identifies a hard epibulbar lesion. The lesion is usually excised to reassure the patient and family of its benign character.

## **NONNEOPLASTIC LESIONS AND DISORDERS SIMULATING MALIGNANT CONJUNCTIVAL NEOPLASMS AND NEOPLASIAS**

A wide variety of completely benign nonneoplastic lesions and disorders can simulate malignant conjunctival neoplasms and neoplasia, including congenital anomalies, degenerative lesions, foreign bodies, various types of inflammatory lesion, secondary acquired pigmentations, and others. In the following section, we mention several of the lesions in this category most commonly mistaken for the three principal types of malignant conjunctival neoplasms and neoplasia.

### **Lesions Simulating Ocular Surface Squamous Neoplasms and Neoplasias**

#### **Conjunctival Hyperplasia**

*Conjunctival hyperplasia* is a noncancerous thickening of the stratified squamous epithelium of the conjunctiva due to abnormal proliferation of epithelial cells.<sup>27</sup> In most cases, some of the transition from columnar basal cells to flattened external surface cells is retained. Histopathologically, the lesion is generally described as *pseudo-adenomatous hyperplasia* (when the thickened epithelium contains dilated "glandular" spaces) and as *squamous cell hyperplasia* (when it does not contain such spaces).

#### **Conjunctival Keratosis/Hyperkeratosis/Dyskeratosis**

*Conjunctival keratosis* is a localized degenerative lesion of the limbal conjunctiva, in which focally abnormal stratified squamous epithelium produces superficial keratin (which is not elaborated by normal conjunctiva).<sup>27,28</sup> A

**Fig. 4.8.24 Actinic Keratosis of Conjunctiva Simulating Ocular Surface Squamous Neoplasia.** This tumor exhibits limited overlying leukoplakia.

**Fig. 4.8.26 Atypical Pinguecula Simulating Ocular Surface Squamous Neoplasia.** This lesion is thickened, exhibits whitish keratinization on its surface and is associated with dilated surrounding conjunctival blood vessels.

**Fig. 4.8.25 Bilateral Hereditary Intraepithelial Dyskeratosis of Conjunctiva Simulating Ocular Surface Squamous Neoplasia.** This lesion resembles squamous cell carcinoma of the conjunctiva quite closely. A similar lesion was present on the fellow eye of this patient.

**Fig. 4.8.27 Pyogenic granuloma of palpebral conjunctiva simulating ocular surface squamous neoplasia.**

lesion of this type is indistinguishable clinically from leukoplakic squamous cell carcinoma (Fig. 4.8.24). When the amount of keratin produced by the conjunctiva at the affected site is prominent, it is referred to as *hyperkeratosis*. *Conjunctival dyskeratosis* refers to nonmalignant aberrant maturation of the conjunctival stratified squamous epithelium associated with thickening of the epithelium and elaboration of keratin. This lesion is most characteristically encountered bilaterally in an autosomal dominantly inherited condition known as *bilateral hereditary intraepithelial dyskeratosis* (Fig. 4.8.25).<sup>29</sup>

#### Inflamed Pinguecula/Hypertrophic Pterygium

*Pinguecula* and *pterygium* are common degenerative conjunctival lesions that usually are easy to distinguish from ocular surface squamous neoplasms and neoplasias. However, atypical pingueculae and pterygia that become inflamed, abnormally thick, and hypervascularized can be difficult to distinguish from squamous cell carcinoma and its variants (Fig. 4.8.26). In addition, conjunctival epithelial dysplasia and invasive neoplasia have been identified histopathologically in association with some prominent pingueculae and pterygia that have been excised. Because of this, all lesions suspected to be an atypical pinguecula or a pterygium that come to excision should be submitted for histopathological analysis.

#### Inflammatory Granuloma of Conjunctiva

A variety of inflammatory tumors of the conjunctiva composed in large part of nonneoplastic chronic and acute inflammatory cells can simulate conjunctival squamous cell carcinoma quite closely. The most common of these is undoubtedly the *pyogenic granuloma* of the conjunctiva.<sup>30,31</sup>

This tumor is a nonneoplastic mass composed of aggregates of immature blood vessels and fibroblastic stroma, accompanied by lymphocytes, plasma cells, and scattered neutrophils. It is believed to be a focally aberrant form of conjunctival healing following an injury (which may be surgical incision). The lesion appears a vascularized pink to red conjunctival tumor that projects abruptly from the conjunctival surface (Fig. 4.8.27). Such lesions frequently recur after a simple excision, and intensive focal anti-inflammatory drug therapy and cryotherapy to the involved conjunctiva coupled with excision often are required to eradicate them. Other inflammatory lesions of the conjunctiva of interest to ophthalmologists include juvenile xanthogranuloma, foreign body granuloma, microbial granuloma (including tuberculoma), and various nonmicrobial inflammatory granulomas associated with systemic condition (e.g., sarcoidosis, lupus).<sup>32-35</sup>

#### Viral Papilloma of Conjunctiva

The *viral papilloma of the conjunctiva* is a reactive inflammatory lesion induced by conjunctival infection by human papilloma virus.<sup>36</sup> The lesion frequently resembles conjunctival squamous papilloma quite closely but is more likely to be multifocal (Fig. 4.8.28) and much more likely to affect young children and adolescents. Attempts to excise such lesions frequently result in exuberant proliferation of new lesions. Cryotherapy to individual lesion is sometimes effective in destroying them. However, recurrent lesions following excision with cryotherapy frequently require supplemental treatment with topical interferon drops or chemotherapeutic drops (mitomycin C, 5-fluorouracil). Some success has also been reported when such lesions were treated by oral cimetidine.

**Fig. 4.8.28** Viral papillomas of conjunctiva simulating papillary conjunctival squamous cell carcinoma.

**Fig. 4.8.30** Uveal prolapse and incarceration in eye wall laceration simulating conjunctival melanoma.

**Fig. 4.8.29** Iridociliary melanoma with anterior transcleral extension simulating conjunctival melanoma.

**Fig. 4.8.31** Nodular Anterior Scleritis Simulating Conjunctival Neoplasm. The conjunctiva and sclera are thickened and hyperemic diffusely, and this lesion was tender to palpation.

## Lesions Simulating Conjunctival Melanoma and Malignant Primary Acquired Melanosis

### Posterior Uveal Melanoma With Anterior Transcleral Extension

Some *uveal melanomas* that involve the ciliary body extend transclerally to the episcleral surface via scleral neural or vascular foramina.<sup>37,38</sup> The epibulbar tumor in such cases usually is dark brown and frequently associated with prominently dilated epibulbar blood vessels (Fig. 4.8.29). The distinguishing feature that is obvious on slit-lamp biomicroscopy is the absence of conjunctival epithelial involvement. Ocular transillumination typically reveals a distinct shadow produced by the ciliary body portion of the tumor. Ocular ultrasonography (possibly UBM) will confirm the presence of the underlying ciliary body tumor.

### Occult Eyewall Laceration With Incarceration of Uveal Tissue

Some individuals who have suffered a conjunctival and *eye wall laceration* will not recognize the extent of their injury and not get evaluated by an eye specialist for weeks to years following that injury.<sup>39</sup> In some such cases, uveal tissue is incarcerated into the wound (Fig. 4.8.30). This uveal tissue can be mistaken for a conjunctival melanoma.<sup>40</sup>

### Nodular Anterior Scleritis

*Nodular anterior scleritis* is a severe inflammatory reaction to some inciting event that develops within the anterior sclera.<sup>41</sup> The eye is painful and the affected area of the sclera and overlying conjunctiva are extremely reddened and thickened (Fig. 4.8.31). The eye is frequently very tender to

palpation of the reddened area through the eyelid. UBM can demonstrate the localized scleral thickening in such cases. Treatment usually consists of corticosteroids and, if necessary, other anti-inflammatory drugs.

### Ciliary Body Staphyloma

The *ciliary body staphyloma* is a localized thinning of the sclera, usually in response to a prior injury or surgery or a prior episode of nodular or necrotizing scleritis, that then bulges as a result of intraocular pressure.<sup>42</sup> In most cases, the lesion appears as a smoothly elevated bluish-brown scleral mass without involvement of the overlying conjunctiva and without prominently dilated epibulbar blood vessels in that location (Fig. 4.8.32). Ocular transillumination shows prominent transmission of light through the eye wall corresponding to the visible dark lesion. UBM can confirm the thinning of the eye wall and absence of any underlying ciliary body tumor.

### Conjunctival Argyrosis

*Conjunctival argyrosis* is an acquired dark gray to black pigmentation of the conjunctiva that develops in response to chronic application of silver nitrate drops.<sup>43</sup> Affected individuals often were given some silver nitrate drops many years ago as treatment for a conjunctival infection and continued to take the drops for years after the original problem resolved. The conjunctival pigmentation can simulate primary acquired melanosis of the conjunctiva quite closely (Fig. 4.8.33).

## Lesions Simulating Conjunctival Lymphoma

### Benign Reactive Lymphoid Hyperplasia of the Conjunctiva

Benign reactive lymphoid hyperplasia (BRLH) of the conjunctiva is a nonmalignant infiltrative mass of the conjunctiva composed principally

**Fig. 4.8.32** Ciliary Body Staphyloma Simulating Conjunctival Melanoma. Note the absence of prominently dilated conjunctival blood vessels associated with this lesion.

**Fig. 4.8.35** Sarcoid granulomas of inferior forniceal and palpebral conjunctiva simulating conjunctival lymphoma.

**Fig. 4.8.33** Argyrosis of conjunctiva simulating primary acquired melanosis of conjunctiva.

**Fig. 4.8.34** Benign lymphoid hyperplasia of conjunctival simulating conjunctival lymphoma.

of benign or mildly atypical lymphocytes.<sup>44</sup> The infiltrate is characterized pathologically by a polyclonal accumulation of benign appearing lymphoid cells, usually in a follicular pattern. The lesion can affect one or both eyes and usually involves the forniceal conjunctiva predominantly (Fig. 4.8.34). It resembles malignant lymphoma quite closely, and only histopathological and immunopathological analysis can distinguish between these entities.

Limited lesions may be left untreated, but extensive lesions of this type usually are treated by low-dose external beam radiation therapy.

### **Inflammatory Granulomas of Conjunctiva**

Certain *inflammatory granulomas of the conjunctiva*, including those caused by microbial organisms (e.g., tuberculoma), nonmicrobial inflammatory disorders (e.g., sarcoid granuloma), and foreign bodies, can resemble malignant lymphoma of the conjunctival quite closely (Fig. 4.8.35).<sup>33-35</sup> Biopsy or excision of the mass with histopathological and microbiological analysis of the specimen generally is required for diagnosis and to guide subsequent patient management.

## **MANAGEMENT OF CONJUNCTIVAL TUMORS SUSPECTED OF BEING MALIGNANT NEOPLASMS OR NEOPLASIAS**

Clinically suspected conjunctival malignant neoplasms and neoplasias usually are managed by surgical excision<sup>45,46</sup> (if possible) or biopsy (if the lesion involves an extensive portion of the conjunctiva) followed by supplemental therapy of the retained conjunctiva by methods such as cryotherapy<sup>47</sup> (liquid nitrogen spray or cryoprobe therapy), topical immunotherapy<sup>48,49</sup> (interferon eyedrops [off-label therapy]), topical chemotherapy<sup>50-52</sup> (mitomycin C or 5-fluorouracil eyedrops [off-label therapy]), or radiation therapy<sup>46,53</sup> (epibulbar strontium-90 applicator therapy, radioactive plaque brachytherapy, or external beam radiation therapy) if malignant neoplasia is confirmed pathologically. The goal of treatment is complete eradication of the cancer cells with preservation of the eye and retention or recovery of good vision. Surgical excision of suspected conjunctival neoplasms and neoplasias should include at least a 1-mm margin of clinically uninvolved conjunctiva around the visible lesion, whenever possible. The ophthalmic surgeon should give thoughtful consideration to closure of the surgical defect by mobilizing the retained conjunctiva around the defect and creating relaxing conjunctival incisions for advancement flaps as needed or arranging for implantation of a mucous membrane (e.g., amniotic membrane) graft when primary closure is impossible.<sup>54,55</sup> In general, lamellar sclerectomy and keratectomy should be avoided, whenever possible, and suspected scleral or corneal invasion by the neoplasia should be managed by supplemental cryotherapy, radiation therapy, or both as indicated subsequent to the excisional procedure.

Because conjunctival melanomas tend to metastasize via lymphatics to lymph nodes in the head and neck, all patients with a newly diagnosed conjunctival melanoma should be evaluated by palpation of the head and neck ipsilateral to the tumor to search for clinically detectable lymph nodes.<sup>56</sup> Those with suspicious lymph nodes by palpation should be evaluated by computed tomography or magnetic resonance imaging of the head and neck to confirm or rule out the physical examination findings. Patients having an extremely large conjunctival melanoma, especially if it involves the fornices or palpebral conjunctiva, and those whose tumor exhibits ulceration and numerous mitotic figures histopathologically<sup>57,58</sup> should be considered for sentinel lymph node mapping and biopsy.<sup>59-61</sup> If melanoma node metastasis is confirmed by biopsy, complete neck dissection with

wider lymph node excision may be considered,<sup>58</sup> and systemic immunotherapy for that metastatic melanoma is likely to be initiated.<sup>62</sup>

In contrast, squamous cell carcinomas and variants and other malignant conjunctival neoplasms rarely metastasize to regional lymph nodes. Consequently, lymph node mapping and sentinel lymph node biopsy generally are not indicated for such neoplasms. Some aggressive and locally advanced conjunctival melanomas, variants of squamous cell carcinoma (especially mucoepidermoid carcinoma), and sebaceous carcinomas of the conjunctiva will have invaded the orbit extensively prior to diagnosis, and such cases may be treated by orbital exenteration if complete excision is not possible.<sup>63,64</sup>

Suspected lymphomas of the conjunctiva warrant a special comment. Optimal current analysis of such lesion involves testing of both fixed tissue and fresh tumor specimens (for flow cytometry and gene rearrangement studies).<sup>9,10</sup> When such lesions are excised or a biopsy performed, the tissue obtained in the procedure should be divided in approximately equal parts in the operating room. One of these specimens should be submitted in formalin for conventional histopathological and immunohistochemical studies. The other half should be submitted as moistened fresh tumor to the pathology laboratory for flow cytometry and gene rearrangement testing. The most common treatment for localized low-grade conjunctival lymphoma is low-dose external beam radiation therapy.<sup>65</sup>

# Pterygium and Conjunctival Degenerations

## 4.9

Roni M. Shtein, Alan Sugar

**Definition:** Secondary deterioration or deposition in the conjunctiva, distinct from dystrophies.

### Key Features

- Common.
- Bilateral usually.
- Typically does not affect vision.

### Associated Features

- Increased prevalence with age.
- Often associated with chronic light exposure.
- May occur after past inflammation.
- Not inherited.

## INTRODUCTION

Degenerations of the conjunctiva are common conditions that, in most cases, have relatively little effect on ocular function and vision. They increase in prevalence with age as a result of past inflammation, long-term toxic effects of environmental exposure, or aging itself. Conjunctival degenerations may be associated with chronic irritation, dryness, or previous history of trauma. Progression to involve the cornea may occur, as in pterygium.

## PINGUECULA

*Pingueculae* are elevated, horizontally oriented areas of bulbar conjunctival thickening that are white to yellow in color and adjoin the limbus in the palpebral fissure area (Fig. 4.9.1). They are less transparent than normal conjunctiva, often have a fatty appearance, are usually bilateral, and are

**Fig. 4.9.1 Nasal Pinguecula.** Elevated conjunctival lesion encroaches on nasal limbus.

located nasally much more often than temporally. When a pinguecula crosses the limbus onto the cornea, it is called a *pterygium*. Current information, however, suggests that pinguecula do not progress to pterygium and that the two are distinctly different disorders. Pingueculae are associated with a two- to threefold increased incidence of age-related macular degeneration, possibly through a common light exposure effect.<sup>1</sup>

The causes of pingueculae are not known with certainty. There is, however, good evidence of an association with increasing age and ultraviolet light exposure. Pingueculae are seen in most eyes by age 70 years and in almost all by age 80 years.<sup>2</sup> Chronic sunlight exposure has been found to be a factor by association with outdoor work and equatorial residence. In some studies, the strength of this association is less than that for pterygium.<sup>3</sup> It is thought that the predominantly nasal location is related to reflection of light from the nose onto the nasal conjunctiva. The effect of ultraviolet light may be mediated by mutations in the *p53* gene.<sup>4</sup>

Pingueculae rarely are associated with symptoms other than a minimal cosmetic defect. They may become red with surface keratinization. When inflamed, the diagnosis of pingueculitis is made.

Distinguishing pingueculae from other lesions usually is not a problem because of the typical appearance. Conjunctival intraepithelial neoplasia may be difficult to differentiate from keratinized pinguecula. Gaucher's disease type I may be associated with tan pingueculae, but this is not a specific finding.<sup>5</sup>

Histopathologically, pingueculae are characterized by elastotic degeneration of the collagen with hyalinization of the conjunctival stroma, collection of basophilic elastotic fibers, granular deposits, and noninvolvement of the cornea.<sup>6</sup>

Pingueculitis responds to a brief course of topical corticosteroids or nonsteroidal anti-inflammatory agents.<sup>7</sup> Chronically inflamed or cosmetically unsatisfactory pingueculae rarely warrant simple excision.

## PTERYGIUM

*Pterygium* is a growth of fibrovascular tissue on the cornea and conjunctiva. It occurs in the palpebral fissure, much more often nasally than temporally, although either or both ("double" pterygium) occur (Fig. 4.9.2). Elevated whitish opacities ("islets of Vogt") and an iron deposition line ("Stocker") may delineate the head of the pterygium on the cornea. Like pinguecula, it is a degenerative lesion, although it may appear similar to pseudo-terygium, which is a conjunctival adhesion to the cornea secondary to previous trauma or inflammation, such as peripheral corneal ulceration. A pseudo-terygium often has an atypical position and is not adherent at all points, so a probe can be passed beneath it peripherally.

Like pinguecula, pterygium is associated with ultraviolet light exposure.<sup>3</sup> It occurs at highest prevalence and most severely in tropical areas near the equator and to a lesser and milder degree in cooler climates.<sup>8</sup> Outdoor work and both blue and ultraviolet light have been implicated in its causation. The use of hats and sunglasses is protective.<sup>8</sup> Theories of pathogenesis of pterygia include the possibility of damage to limbal stem cells by ultraviolet light and by activation of matrix metalloproteinases.<sup>9</sup> The histopathology of pterygium is similar to that of pinguecula except that Bowman's membrane is destroyed within the corneal component and vascularization is seen.<sup>9</sup> Evaluation using spectral domain optical coherence tomography reveals pterygium as an elevated, wedge-shaped mass of tissue separating the corneal epithelium from Bowman's membrane, which appears abnormally wavy and interrupted and often destroyed, with satellite masses of subepithelial pterygium tissue beyond the clinically seen margins.<sup>10</sup>

**Fig. 4.9.2 Double Pterygium.** (A) Note both nasal and temporal pterygia in a 57-year-old farmer. (B) It is the invasion of the cornea that distinguishes a pterygium from a pinguecula.

Pterygia warrant treatment when they cause discomfort (not responsive to conservative therapy), encroach upon the visual axis, induce significant astigmatism, or become cosmetically bothersome. Aggressive or recurrent pterygia may cause restrictive strabismus and distortion of the eyelids. A variety of surgical techniques have been developed. The goal of treatment is prevention of recurrence. The recurrence rates after simple excision are very high: Of recurrences, 50% reoccur within 4 months of excision and nearly all within 1 year.<sup>11</sup> Beta-radiation applied postoperatively to the pterygium base was popular for many years but is associated with late scleral necrosis.<sup>12</sup> Currently, the most widely used techniques are conjunctival autografting and amniotic membrane transplantation.<sup>12</sup> Adjuvant use of mitomycin-C application—either pre-, intra-, or postoperatively—has been associated with scleral melt in some situations.<sup>13</sup> Fibrin-based glues have been used to minimize operating time and discomfort associated with sutures, and to reduce the amount of suturing required.<sup>14</sup>

## SENILE SCLERAL PLAQUES

Senile scleral plaques occur in the sclera of elderly patients and often are misinterpreted as a melting process similar to that of corneal degenerations or as conjunctival depositions. These lesions appear as yellow, gray, or black vertical bands just anterior to the insertion of the medial and lateral rectus muscles (Fig. 4.9.3). They become more common after age 60 years and, like pinguecula and pterygium, may be related to ultraviolet light exposure.<sup>15</sup> Histologically, calcium deposits along with decreased cellularity and hyalinization are seen. These lesions do not need therapy.

## CONJUNCTIVAL AMYLOID

Deposition of amyloid in the conjunctiva has been reported in both primary and secondary localized forms (Fig. 4.9.4) and secondary to systemic processes.<sup>16</sup> Chronic conjunctival inflammation may cause secondary localized amyloidosis, a true degenerative change. In the primary localized forms, light-chain immunoglobulins deposited by monoclonal B cells and plasma cells have been demonstrated by immunohistochemistry.

**Fig. 4.9.3 Senile Scleral Plaque.** Calcium deposition appears as a gray scleral plaque under the medial rectus muscle insertion.

**Fig. 4.9.4 Primary Localized Conjunctival Amyloid.** There is irregularity of the conjunctiva superonasally with fixed folds. Resolving subconjunctival hemorrhages noted superiorly are associated with amyloid deposition in blood vessel walls.

In lesions secondary to systemic disease, other forms of amyloid protein may be seen.<sup>17</sup> All patients should be evaluated for lymphoproliferative and systemic diseases. Amyloid involving the skin of the eyelids has been suggested to be a sign of systemic involvement.<sup>18</sup>

Conjunctival amyloid may appear as a yellowish, well-demarcated, irregularly elevated mass. It generally involves the fornices, with the superior fornix and tarsal conjunctiva most commonly affected. In vivo confocal microscopy of conjunctival amyloid shows hyporeflective material in a lobular pattern in the substantia propria and around the blood vessels in the conjunctiva without associated inflammation.<sup>19</sup> Recurrent subconjunctival hemorrhages may be associated with amyloid deposition in blood vessel walls. Biopsy is required for definitive diagnosis.<sup>17</sup>

Lesions generally are treated symptomatically, although debulking excision can be performed for chronic irritation. Although it may not cause full regression of deposited amyloid, radiotherapy may be used to prevent progression.<sup>20</sup>

## CONJUNCTIVAL MELANOSIS

Conjunctival melanosis is a common finding with advancing age. The appearance is that of a flat, pigmented area on the conjunctiva. Primary acquired melanosis is a risk factor for development of conjunctival melanoma and is discussed in detail in Chapter 4.8.

Secondary melanosis of the conjunctiva is generally benign and tends to be more frequently bilateral. Secondary melanosis occurs following trauma, chronic inflammation of the conjunctiva, and in individuals with darker skin pigmentation.<sup>21</sup> Secondary melanosis generally is not associated with atypia and can be observed. If the lesions are noted to be elevated or where uncertainty exists, biopsy should be performed.

# Ocular Cicatricial Pemphigoid/Mucous Membrane Pemphigoid

Ahmed Al-Ghoul, Steven Kane, Deepinder K. Dhaliwal

4.10

**Definition:** A heterogeneous group of chronic, systemic, inflammatory, subepithelial, blistering diseases.

### Key Features

- Subepithelial bulla formation, rupture, and scarring of mucous membranes and skin.
- Female-to-male ratio of 2:1.
- Type II immune linear deposition of immunoglobulin A (IgA), IgG, IgM, and/or complement (C3) on the conjunctival epithelial basement membrane.
- Systemic immunosuppressive treatment is critical in suppressing conjunctival inflammation and disease progression.

### Associated Features

- Be aware of the significant extraocular morbidities that can occur, such as esophageal stricture formation.
- Surgical management of ocular cicatricial pemphigoid traditionally carries a poor prognosis.

## INTRODUCTION

Ocular cicatricial pemphigoid (OCP) is an autoimmune disease characterized by chronic progressive conjunctival inflammation and scarring. This condition belongs to a heterogeneous group of chronic, systemic, inflammatory, subepithelial, blistering diseases termed mucous membrane pemphigoid.<sup>1</sup> They share the similar manifestations of subepithelial bulla formation, rupture, and scarring of mucous membranes and skin.<sup>2</sup>

The incidence of mucous membrane pemphigoid varies between 1 in 20000 to 1 in 46000 in the ophthalmic literature, with a female-to-male ratio of approximately 2:1.<sup>2</sup> The average age of diagnosis is in the seventh decade of life (age range 30–90 years), and an average diagnostic lag of 2.8 years has been reported because of the nonspecific nature of early disease.<sup>3,4</sup> No racial or geographical predilection has been reported. Oral involvement in mucous membrane pemphigoid occurs in up to 84% of cases. The risk of ocular disease in patients seen with only extraocular manifestations is estimated to be 5% per annum for the first 5 years of follow-up with eventual involvement in up to 80% of cases.<sup>5,6</sup> Approximately 50% of patients presenting with OCP will have extraocular lesions.<sup>7</sup> The clinical presentation and frequency of extraocular tissue involvement is listed in Table 4.10.1.

## PATHOGENESIS

Although the cause of mucous membrane pemphigoid remains unknown, research continues to unravel more clues as to the pathogenesis of this complex condition. The hallmark of this autoimmune disease is the type II immune linear deposition of immunoglobulin A (IgA), IgG, IgM, and/or complement (C3) on the conjunctival epithelial basement membrane. Autoantibodies form against different components of the basement membrane, with certain autoantigens being more specific for particular mucosal regions in the body. This likely explains the clinical heterogeneity seen in mucous membrane pemphigoid.<sup>8</sup> Multiple target autoantigens,

TABLE 4.10.1 Clinical Features and Frequency in Mucous Membrane Pemphigoid

Site	Clinical Features	Frequency (%)
Oral mucosa and pharynx	Oral mucosal vesicles/bullae Desquamative gingivitis Pharyngitis and scarring	30–84
Conjunctiva	Conjunctivitis and progressive scarring	60–80
Nose/sinus	Epistaxis Nasal mucosa/turbinate ulcers	18–50
Skin	Localized, erythematous plaques with recurrent vesicles and bullae on the scalp and face that heal with atrophic scars Recurrent vesiculobullous eruptions of the inguina and/or extremities	17–23
Esophagus	Dysphagia Esophageal strictures	7–27
Larynx	Intermittent hoarseness or dysphonia Supraglottic inflammation and scarring	5–30
Anus/vagina	Blisters, erosions, and scarring with or without fusion of tissues	5–11

Benign mucous membrane pemphigoid. *Arch Dermatol* 1971;104:467–75; and Elder MJ, Lightman S. The immunological features and pathophysiology of ocular cicatricial pemphigoid. *Eye* 1994;8:196–9.

including BP180, BP230,  $\alpha_6 \beta_4$  integrin, laminin 5, and type VII collagen, have been identified in patients with mucous membrane pemphigoid. In particular,  $\alpha_6 \beta_4$  integrin has been strongly linked with OCP. This antigen is an important component of hemi-desmosomes required for epithelial cell attachment to the basement membrane, and its targeting may explain the formation of subepithelial bullae seen in OCP.<sup>9</sup> Recent studies have shown abnormal serum levels of interleukin-4 (IL-4), IL-5, IL-6, tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and transforming growth factor-beta (TGF- $\beta$ ) during the active phase of the disease, suggesting an abnormal immune system regulation. Further support for the autoimmune nature of mucous membrane pemphigoid comes from the observed association with other autoimmune diseases, such as rheumatoid arthritis, systemic lupus erythematosus, and polyarteritis nodosa.<sup>3,10</sup> A genetic predisposition for developing mucous membrane pemphigoid also has been postulated by linkage studies. Specific human leukocyte antigen (HLA) class II alleles, such as the DQB1\*0301, are significantly associated with severe disease phenotype and anti-basement membrane zone IgG antibody response in mucous membrane pemphigoid.<sup>1</sup>

The histopathology of OCP demonstrates local infiltration by macrophages, neutrophils, T cells, mast cells, and eosinophils into the conjunctiva.<sup>2,11</sup> The presence of these cells in conjunction with antibody/complement deposition results in the inflammatory response with subsequent bullae formation, rupture, and eventual scarring.

## CLINICAL FINDINGS

Ocular cicatricial pemphigoid presents with nonspecific symptoms of irritation, burning, and tearing and can manifest as recurrent papillary

**Fig. 4.10.1** Stage I ocular cicatricial pemphigoid (OCP) characterized by conjunctival subepithelial scarring.

**Fig. 4.10.2** Stage II ocular cicatricial pemphigoid (OCP) characterized by forniceal foreshortening.

**Fig. 4.10.3** Stage III ocular cicatricial pemphigoid (OCP) characterized by symblepharon formation.

conjunctivitis. In some cases, patients do not experience ocular symptoms even with advanced signs of conjunctival scarring. The ocular involvement initially can be unilateral but progresses, usually within 2 years, to bilateral involvement with asymmetry in the severity and rate of evolution.<sup>4,12</sup>

The disease progression of OCP has classically been documented into one of four stages (Figs. 4.10.1–4.10.4).<sup>4</sup> Stage I denotes chronic conjunctivitis with subepithelial fibrosis and an unstable tear film. This leads to dryness and exacerbation of the cicatrization process.<sup>2,12,13</sup> Stage II refers

**Fig. 4.10.4** Stage IV ocular cicatricial pemphigoid (OCP) showing end-stage findings of keratinization of the ocular surface and ankyloblepharon.

to inferior fornix foreshortening. Stage III describes symblepharon formation typically starting with the inferior fornix. As a result of the cicatrizing process, lid abnormalities become a major confounder in the overall prognosis. Trichiasis, entropion, and lagophthalmos contribute to the exposure and abrasion of the corneal surface.<sup>12</sup> Damage to mucin-producing goblet cells, meibomian glands, and lacrimal glands leads to keratinization, which along with ankyloblepharon formation and corneal scarring define the end-stage, which is stage IV. As such, in addition to staging disease progression, the extent of conjunctival inflammation should be graded from inactive (0) to severe (4+).<sup>4</sup> By assessing the stage of the disease process and degree of conjunctival inflammation, appropriate therapy for these patients can be determined more accurately.

## DIAGNOSIS

Early diagnosis is the key to preventing the blinding consequences of OCP. The diagnosis ideally rests on both clinical suspicion and immunopathology of biopsied conjunctiva and/or other involved tissues.<sup>14</sup> Biopsy using immunopathological techniques provides the only definitive evidence of ocular cicatricial pemphigoid, and should encompass an area with both inflamed and noninflamed tissues. Active oral lesions may be biopsied to aid in diagnosis.<sup>15</sup> Tissue samples should be fresh or fixed in Zeus' or Michel's fixative for no more than 5 days.<sup>1</sup> Linear deposition of IgG, IgA, IgM, and/or complement (C3) at the epithelial basement membrane zone of inflamed conjunctiva is seen using direct immunofluorescence (DIF) techniques, with a sensitivity between 20% and 84%.<sup>2,16</sup> If the DIF study findings are negative and the clinical suspicion is high, a more sensitive test, such as the immunoperoxidase assay, should be employed.<sup>1</sup> To date, indirect immunofluorescent testing to detect circulating autoantibodies in patients' sera has a limited role. Newer serological tests that show promise in the diagnosis of mucous membrane pemphigoid are being developed.<sup>3</sup> Serum and saliva IgG and IgA antibodies may be helpful diagnostic markers and have shown high positive predictive value.<sup>17</sup>

In making the diagnosis of OCP, other causes must be considered. Adenovirus and herpes simplex virus infections, chlamydia, diphtheria, gonorrhea, and beta-hemolytic *Streptococcus* infection can all cause a membranous conjunctivitis that results in conjunctival scarring. Radiation, thermal, and chemical burns, as well as mechanical or surgical trauma, can cause conjunctival shrinkage and symblephara. Systemic practolol and D-penicillamine and topical epinephrine, echothiophate iodide, and pilocarpine all have been associated with inducing ocular pemphigoid-like features. Allergic and inflammatory conditions, such as atopic and rosacea keratoconjunctivitis, respectively, as well as systemic conditions such as Sjögren's syndrome, sarcoidosis, and progressive systemic sclerosis also can present as cicatrizing conjunctivitis. Other autoimmune diseases, such as pemphigus vulgaris, erythema multiforme, Stevens–Johnson syndrome, toxic epidermal necrolysis, epidermolysis bullosa acquisita, lichen planus, dermatitis herpetiformis, and linear IgA disease, among others, are associated with cicatrizing conjunctivitis to varying degrees. Biopsy results in addition to clinical history, presentation, and course can help distinguish all of these differential diagnoses from the systemic, chronic, progressive, and bilateral ocular cicatricial pemphigoid.<sup>1–3,5</sup>

## TREATMENT

The goal of therapy in OCP is to suppress inflammation, promote healing, and prevent cicatrization. Local measures include the use of lubricating drops, punctal occlusion, autologous serum, and contact lenses for the dry eye component, and lid hygiene and oral tetracyclines for the blepharitis, and epilation for trichiasis management.

Systemic immunosuppressive treatment for OCP is critical to prevent the otherwise invariable progression to conjunctival and corneal scarring and eventual blindness. The use of such agents is particularly challenging because patients usually are older, the disease is chronic, other extraocular tissues can be involved, and the systemic immunosuppressive agents required to control the disease have many side effects. In addition, the majority of patients are diagnosed late in the course of the disease, thus requiring aggressive and long-term therapy.<sup>18</sup> Therefore, the use of systemic agents should be co-managed with the patient's primary care physician, rheumatologist, or oncologist.

Clinical studies regarding systemic therapy in OCP remain limited. When choosing an immunosuppressive agent, the stage of ocular disease and the degree of inflammation should be considered. Although dapsone and sulfasalazine were historically the first-line treatment for mild to moderate inflammation, other immunosuppressive agents have shown better efficacy and fewer side effects. Mycophenolate mofetil may be a better first-line agent of choice for OCP presenting without sight-threatening complications.<sup>19–21</sup> Methotrexate also may be a good first-line option, although it may have more side effects (including hepatic and pulmonary fibrosis) compared with mycophenolate mofetil.<sup>22</sup> For vision threatening, progressive OCP cyclophosphamide, either alone or in conjunction with prednisone, may be the treatment of choice.<sup>7,23,24</sup> Use of low-dose intravenous pulses of cyclophosphamide, according to the findings of the Euro-Lupus trials, may improve the side-effect profile.<sup>25</sup> Given their dangerous long-term side-effect profile, systemic corticosteroids should only be used as a temporizing measure until other immunomodulatory medications take effect.<sup>5</sup> Options to achieve remission for patients with contraindications or adverse reactions to conventional treatment or who failed conventional therapy include intravenous immunoglobulin and rituximab.<sup>26–29</sup> Biological agents may be considered in patients whose conditions are resistant to cyclophosphamide. Anti-TNF- $\alpha$  medications including etanercept, infliximab, and pentoxifylline have shown benefit.<sup>15,21</sup>

Surgical management of OCP traditionally has carried a poor prognosis.<sup>12</sup> It is important to completely suppress the inflammatory component of the disease prior to surgical intervention. Repairing trichiasis and entropion helps reduce ocular surface irritation and decompensation. Corneal transplantation for scarred and opaque cornea, ocular surface reconstruction with limbal stem cell transplantation and amniotic membrane

transplantation, and type I Boston keratoprosthesis implantation for visual rehabilitation are potential surgical options but are often unsuccessful as a result of the autoimmune inflammatory nature of the disease.<sup>5</sup> A type II Boston keratoprosthesis or osteo-odonto-keratoprosthesis, each with its own set of complications, can be a limited, but viable, last resort.<sup>30</sup>

## CONCLUSIONS

The prognosis of OCP depends on how soon diagnosis and treatment is initiated. Up to 60% of patients diagnosed with OCP are at an advanced stage (stage III or more) at the time of diagnosis. Nevertheless, control of the ocular inflammation in OCP can be achieved in up to 90% of patients when appropriately treated.<sup>31</sup> Because of the generalized mucosal involvement of this disease, one should be aware of the significant extraocular morbidities that can occur. In particular, esophageal stricture formation can be fatal secondary to reflux into the trachea.<sup>2</sup>

In summary, ocular cicatricial pemphigoid remains a very difficult condition to treat as a result of its progressive autoimmune nature and the lack of sensitive techniques to detect the disease at earlier stages. As newer diagnostic techniques and therapeutic options evolve, the overall outcome for patients will continue to improve.

# Episcleritis and Scleritis

Sarju S. Patel, Debra A. Goldstein

# 4.11

**Definition of Episcleritis:** Inflammation of the connective tissue between the sclera and the conjunctiva.

## Key Features

- Self-limiting.
- Less painful than scleritis.
- Blanches with topical neosynephrine.
- Does not cause damage to the globe.

## Associated Feature

- Systemic association in less than one third of patients.

**Definition of Scleritis:** A disorder of inflammation and necrosis centered on the sclera.

## Key Features

- Focal or diffuse redness or violaceous discoloration.
- Scleral thickening, acutely.
- May develop scleral thinning.
- Nodules.
- Necrosis.
- Pain.

## Associated Features

- Rheumatoid arthritis, granulomatosis with polyangiitis (Wegener's granulomatosis), other vasculitic/connective tissue diseases.
- Keratitis and iritis.
- Glaucoma.
- Exudative retinal detachment.

## INTRODUCTION

The sclera is a dense, poorly vascularized connective tissue structure composed of collagen, elastin, proteoglycans, and glycoproteins. It is embryologically derived from the neural crest and the mesoderm.

The sclera may be affected by a number of inflammatory and noninflammatory processes. This chapter will describe episcleritis, focusing on scleritis, a more serious and often vision-threatening condition.

### Episcleritis

#### Epidemiology and Pathogenesis

*Episcleritis* refers to inflammation of the loose connective tissue between the sclera and the conjunctiva. Patients often complain of discomfort or irritation rather than true pain. Slit-lamp microscopic examination usually localizes any edema to the area that overlies the sclera. The sclera itself is not thickened. Accompanying uveitis is very rare.

Episcleritis is a self-limiting condition, generally running its course in a few days, although nodular disease may last for weeks. Recurrence is common, but structural damage to the eye does not occur.

#### Diagnosis and Ocular Manifestations

Episcleritis can be described as *simple*, in which all or part of the episclera is diffusely inflamed, or *nodular*, in which inflammation is confined to a localized area with the presence of well-defined, red nodules. Nodular episcleritis often is associated with a more discomfort and a more prolonged course compared with simple episcleritis. Bilateral inflammation is seen in 40% of patients.<sup>1</sup> Topical phenylephrine blanches overlying conjunctival vessels and inflamed episcleral vessels.

#### Differential Diagnosis

The differential diagnosis includes conjunctivitis, which is more superficial; phlytenulosis, which is typically mobile; and scleritis, which is deeper and more painful.

#### Systemic Associations

An underlying cause for episcleritis is found in approximately one third of cases.<sup>1,2</sup> In two series of 94 and 85 patients with episcleritis, 68%–73% were found to have no associated disease; 13%–15% had a connective tissue or vasculitic disease; 7% had rosacea; 1%–7% had atopy; and 1%–6% had an associated infection (herpes zoster, herpes simplex, cat scratch disease, Lyme disease).<sup>1,2</sup>

#### Treatment

Some patients may benefit from treatment for cosmesis or alleviation of discomfort. Many physicians elect to treat with topical corticosteroids, demonstrated in a randomized double-masked trial to be superior to placebo for the treatment of episcleritis.<sup>3</sup> However, the use of topical corticosteroids may be detrimental because of the risk of rebound inflammation when the drugs are tapered.<sup>2</sup> Some patients respond well to topical nonsteroidal anti-inflammatory drugs (NSAIDs). Systemic NSAIDs also may be used for the treatment of severe or recurrent episcleritis, although significant side effects may be associated with their use (see section on [scleritis](#)). Treatment of underlying blepharitis is important.

### Scleritis

#### Epidemiology and Pathogenesis

Scleritis is more associated with different systemic diseases compared with uveitis, so the evaluation and treatment for both conditions differ. In most cases, scleral inflammation is noninfectious. However, scleral infection caused by bacterial, protozoan, or fungal organisms, such as *Pseudomonas*, *Mycobacterium*, *Acanthamoeba*, or *Aspergillus*, may cause severe scleritis that is difficult to treat (Fig. 4.11.1). Scleritis typically occurs in the sixth decade of life, but may occur in adolescents and in very old adults. Females are more commonly affected, and bilateral inflammation occurs in nearly 40% of cases.<sup>1</sup>

#### Ocular Manifestations

Scleritis may be unilateral, bilateral, or alternate from eye to eye. The duration of inflammation is variable and may last only a few months or persist for years. The involved area may appear violaceous because the inflammation occurs in deeper tissues (Fig. 4.11.2). The whole eye may be involved, or inflammation may localize to one or more quadrants. The involved area usually is tender to palpation, although pain may occur in seemingly uninvolved areas. The pain typically is deep and boring in nature and often wakes the patient from sleep.

On slit-lamp microscopy, the overlying conjunctival vessels usually are found to be engorged. The episclera may be edematous and inflamed. At times, the secondary inflammation in the conjunctiva and episclera makes it difficult to appreciate the underlying scleral inflammation. Topical

**Fig. 4.11.1** (A,B) Tuberculous scleritis. Note yellow necrotizing nodules in two patients with mycobacterial scleritis. Both patient spontaneously perforated and required enucleation, despite four-drug therapy for tuberculosis and concomitant immunomodulatory therapy. (C) Necrotizing *Acanthamoeba* sclerokeratitis in a 72-year-old female. Note the diffuse deep injection, the area of profound scleral thinning superiorly and active necrotizing, nodular scleritis nasally.

**Fig. 4.11.2** Scleritis With a Violaceous Hue Caused by Deep Inflammation. Vessels do not blanch with topical phenylephrine.

**Fig. 4.11.3** Diffuse scleritis in a patient with rheumatoid arthritis (A). Note that on anterior segment optical coherence tomography, there is diffuse scleral thickening with normal globe contours in the affected area compared with the adjacent unaffected sclera (B).

phenylephrine blanches the overlying conjunctiva and, to a much lesser extent, the episclera and may permit better delineation of the depth of inflammation. The red-free (green) light on the slit lamp may be used to determine the level of inflammation.

Anterior scleritis is classified as diffuse (Fig. 4.11.3A) or nodular (Fig. 4.11.4). It also may be necrotizing or nonnecrotizing. Necrotizing scleritis usually is extremely painful and presents with areas of avascularity in the sclera. Avascular areas may result in scleral thinning, which can progress to staphyloma formation and exposure of bare uvea (Fig. 4.11.5). A simple grading system for scleritis, which has been described in the literature, has helped standardize the assessment of scleritis (Fig. 4.11.6).<sup>4</sup>

**Fig. 4.11.4 Large Scleral Nodule of Undetermined Etiology.** Note the yellow area, which probably represents scleral necrosis (A). A representative anterior segment optical coherence tomography image also illustrates a very thickened and disorganized sclera with a central zone of activity and possible necrotic activity (B).

*Scleromalacia perforans* is a very rare type of painless necrotizing scleritis, which typically occurs in women with a long-standing history of rheumatoid arthritis.

*Posterior scleritis* refers to inflammation behind the equator of the globe and may be difficult to diagnose if anterior scleritis is not also present. Symptoms of posterior scleritis may include pain, blurred vision, and photophobia, although the patient may be fairly asymptomatic. Some patients with posterior scleritis develop proptosis, shallowing of the anterior chamber, exudative retinal detachments, choroidal detachments, disc swelling, and chorioretinal changes (Figs. 4.11.7A and 4.11.8A). Chorioretinal changes may consist of subretinal exudates and hemorrhages, as well as a stippled appearance to the retinal pigment epithelium in long-standing disease.

Scleral inflammation may cause structural damage to the eye, resulting in scleral translucency and thinning (see Fig. 4.11.5). Ocular complications were encountered in nearly 45% of cases in one study, including anterior uveitis (26%), decreased vision (16%), peripheral keratitis (13%), and ocular hypertension (14%).<sup>1</sup> Decreased vision is associated most with necrotizing and posterior scleritis, although vision may be decreased as a result of cystoid macular edema in any type of scleritis. Significant amounts of induced astigmatism necessitate performance of retinoscopy in all patients with anterior scleritis and reduced vision.

Scleritis adjacent to the cornea may be associated with a focal or diffuse keratitis. Focal keratitis may manifest as a ring infiltrate at the limbus, without the peripheral clear zone that is seen with staphylococcal marginal infiltrates (Fig. 4.11.9). Sclerokeratitis also may present with crystalline

**Fig. 4.11.5 Inactive Necrotizing Scleritis in a Patient With Long-Standing Rheumatoid Arthritis.** The patient has had episodes of marked inflammation, but the disease has been quiescent on long-term immunosuppressive therapy.

deposits that have the appearance of spun sugar or cotton candy in the deep cornea (Fig. 4.11.10). This variant is known as *sclerosing keratitis*.<sup>5</sup>

A number of mechanisms may result in elevation of intraocular pressure (IOP). Inflammatory cells may block scleral emissary vessels, which results in elevated episcleral venous pressure and hence elevated IOP. Ciliary body effusion may cause angle closure as the lens-iris diaphragm rotates anteriorly. Accompanying uveitis may be responsible for glaucoma if the trabecular meshwork is clogged with inflammatory cells and debris. Corticosteroid use may result in secondary elevation of IOP.

### Differential Diagnosis

Conjunctivitis usually can be differentiated from scleritis by the presence of discharge, superficial inflammation, and the lack of severe aching or pain. Episcleritis may sometimes be confused with scleritis, although the two conditions can usually be differentiated based on history and clinical examination.

Ciliary flush (injection) that accompanies acute iritis may be confused with scleritis. However, the ciliary flush usually is restricted to the area adjacent to the limbus, and iritis appears to be the predominant finding.

Solid-appearing subretinal masses that mimic melanomas can occur in patients with scleritis (Fig. 4.11.11).<sup>6,7</sup> Computed tomography (CT) may be helpful in making the diagnosis of scleritis in these cases, demonstrating a contrast-enhancing mass that is uniformly isodense with sclera. A-scan ultrasonography usually demonstrates high internal reflectivity in scleritis (as opposed to low internal reflectivity in melanoma), and a B-scan may demonstrate thickened sclera.

### Diagnosis and Ancillary Testing

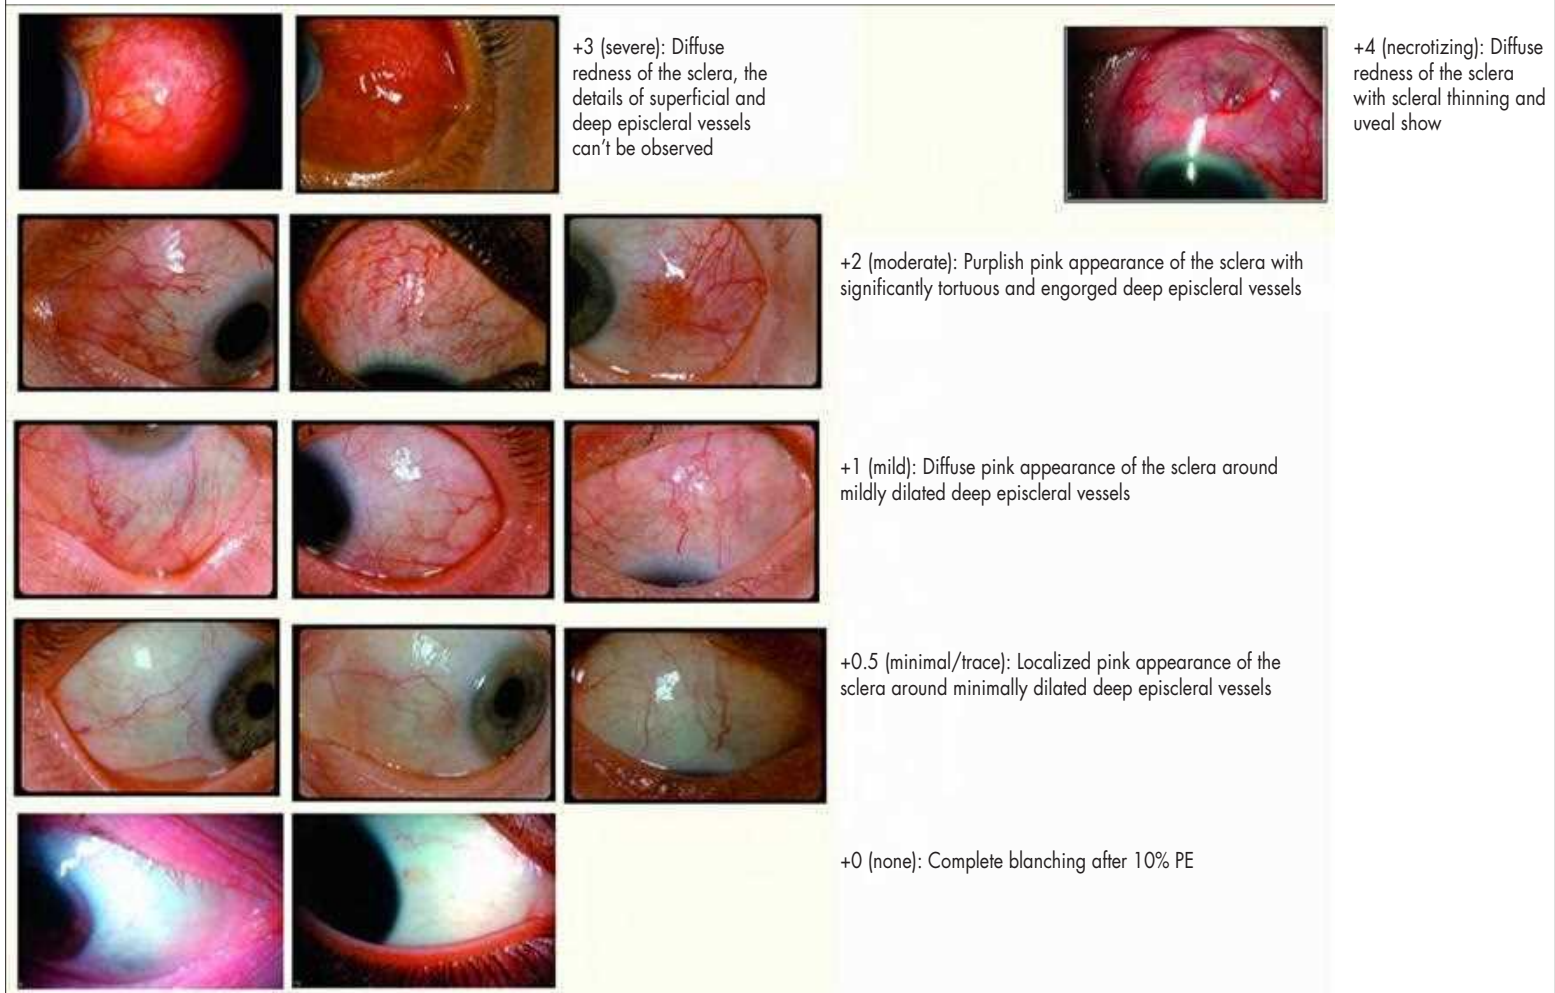

The diagnosis of anterior scleritis is clinically based. It is important to examine the patient with the room lights on. The lid should be lifted and the eyes examined from a distance, as scleritis may be missed if the patient is examined only at the slit lamp in a dark room.

The diagnosis of posterior scleritis can be difficult. Fluorescein angiography may be helpful because it may demonstrate characteristic subretinal leakage spots that coalesce as the study progresses (see Fig. 4.11.8B). Only Vogt-Koyanagi-Harada syndrome has a similar picture on fluorescein angiogram.<sup>8</sup>

B-scan ultrasonography is extremely useful in the diagnosis of posterior scleritis. The T-sign, representing fluid in Tenon's capsule, is highly characteristic of posterior scleritis, although it is not always present (see Fig. 4.11.7C). Thickening of the posterior sclera usually can be demonstrated on B-scan.<sup>9</sup> CT of the orbits with contrast material may show the so-called ring sign of enhancement of the sclera, suggestive of posterior scleritis. Magnetic resonance imaging has not proved to be any more useful than CT and may even be less helpful,<sup>10</sup> although it avoids the radiation risks associated with CT. Ultrasound biomicroscopy and anterior segment optical coherence tomography may help characterize severity and extent of disease (see Figs. 4.11.3B and 4.11.4B).<sup>11</sup>

The workup of a patient with scleritis includes an evaluation for systemic vasculitis, connective tissue disease, and infection. Much of this information can be gained from a detailed history. Laboratory tests might

### Scleritis Grading (Following 10% Phenylephrine application)

**Fig. 4.11.6** Standardized grading system for scleritis. (Reproduced from Sen HN, Sangave AA, Goldstein DA, et al. A standardized grading system for scleritis. *Ophthalmology* 2011;118:768–71.)

include erythrocyte sedimentation rate, rheumatoid factor, anticitrullinated protein antibody, antineutrophil cytoplasmic antibodies (C- and P-ANCA), antiproteinase 3, antimyeloperoxidase antibodies (anti-PR3, anti-MPO), and antinuclear antibody. Review of systems and a relevant family history may prompt the clinician to order human leukocyte antigen B27 or inflammatory bowel serology. Specific serological test for syphilis (including fluorescent treponemal antibody absorption test, microhemagglutination test for *Treponema pallidum*, syphilis immunoglobulin G enzyme immunoassay) should be obtained for all patients with ocular inflammation. A complete blood count and urinalysis may be considered. Chest radiography may be performed to look for evidence of tuberculosis, sarcoid, or granulomatosis with polyangiitis (GPA). ANCA, anti-PR3, and anti-MPO testing often is positive in cases of GPA, microscopic polyarteritis, and other related vasculitides.<sup>12</sup> Two different patterns of immunofluorescence staining have been identified. Classic ANCA (C-ANCA) and anti-PR3 are more specific for GPA and other closely related vasculitides. The positivity of this test may depend, in part, on disease activity; in some patients, the test becomes negative with treatment or a decrease in disease activity.<sup>13</sup>

#### Systemic Associations

Underlying systemic disease is present in approximately 35%–50% of patients with scleritis.<sup>1,14</sup> Rheumatoid arthritis is the most frequently associated condition,<sup>15</sup> and scleritis may be the first manifestation, preceding joint disease.<sup>16</sup> Other connective tissue diseases that can present with scleritis include GPA, polyarteritis nodosa, systemic lupus erythematosus, and relapsing polychondritis (Fig. 4.11.12).

Psoriatic arthritis and ankylosing spondylitis, although usually associated with acute iritis, can at times be associated with scleritis.<sup>15</sup> Inflammatory bowel disease, especially Crohn's disease, can be associated with

scleritis. Scleritis has been observed in 18% of patients with inflammatory bowel disease and may correspond to gastrointestinal (GI) disease activity, as does accompanying large joint peripheral arthritis.<sup>17</sup> Pyoderma gangrenosum and Cogan's syndrome can be associated with scleritis.<sup>18</sup> Sarcoidosis can cause granulomatous scleritis.

Infectious conditions, such as tuberculosis, acanthamoebiasis, syphilis, and leprosy, may result in granulomatous, nodular scleritis (see Fig. 4.11.1A). Herpes zoster and herpes simplex may cause scleritis (Fig. 4.11.13). When herpesviruses cause scleritis, it usually is in the late recovery phase of the disease rather than during acute infection.<sup>14</sup>

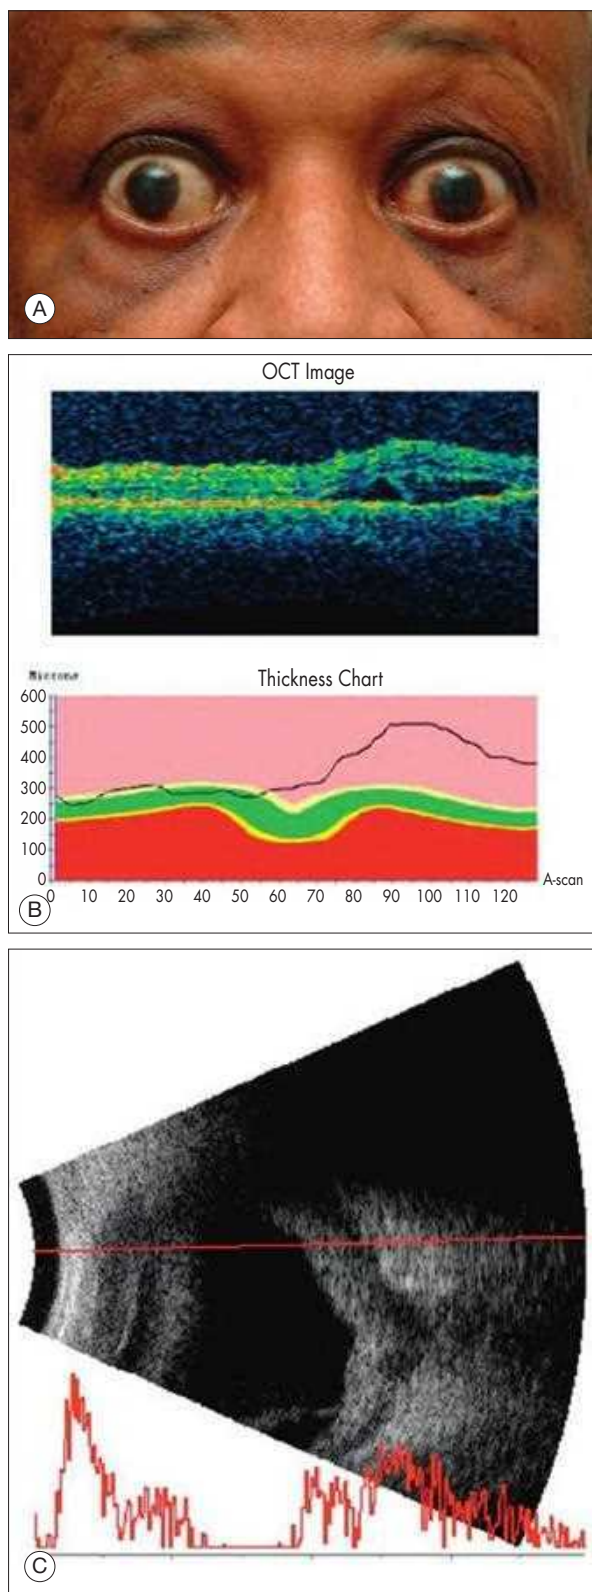

Necrotizing scleritis can be triggered by ocular surgery (Fig. 4.11.14); it has been reported weeks to months after cataract surgery, penetrating keratoplasty, muscle surgery, glaucoma surgery, and even pterygium surgery.<sup>19–21</sup> Evidence exists of underlying connective tissue disease in some of these patients, but in others, no causative factor can be found. Infectious causes must be sought in all patients with postoperative scleritis.

#### Pathology

Scleral biopsy should be done only in exceptional circumstances. The surgeon should be prepared either to place a scleral reinforcement graft or use some other tissue, such as periosteum, to replace the sclera that has been sampled for biopsy, as severe thinning of the sclera can result in an unexpected encounter with intraocular contents.

Histopathological examination may reveal one of four patterns of inflammation, which can correlate with disease etiology<sup>22,23</sup>: zonal, necrotizing granulomatous; diffuse, nonnecrotizing; necrotizing with microabscesses; and nonzonal, nondiffuse granulomatous. Antigen–antibody complexes mediate zonal, necrotizing granulomatous inflammation, which is most often associated with systemic disease.<sup>22,23</sup> Lymphocytes

**Fig. 4.11.7** (A) A 72-year-old male with bilateral posterior scleritis. Note the bilateral proptosis. (B) Optical coherence tomography demonstrating subretinal fluid. (C) B-scan demonstrating T-sign, and marked choroidal thickening. The T-sign is believed to be due to fluid in Tenon's capsule and is very characteristic of posterior scleritis, although it is not always present.

and plasma cells appear in diffuse nonnecrotizing inflammation, which is often idiopathic.<sup>22,23</sup> Necrotizing inflammation with microabscesses is observed in infectious scleritis.

## Treatment

### Medical Treatment

Most patients who have active scleritis require therapy. Some physicians recommend that treatment be continued until all redness is gone from the eye. However, if no pain and no evidence of any damage to the eye exist, the side effects of the therapy may outweigh the benefits. Some patients

who have only mild redness, no active secondary uveitis or keratitis, and no visual problems may not require therapy, but must be closely monitored.

Topical nonsteroidal agents may be of some benefit in patients who have mild episcleritis, but they are of no benefit in true scleritis. Most topical corticosteroids do not have any marked beneficial anti-inflammatory effect in cases of true scleritis, although they may be helpful in controlling secondary uveitis. Difluprednate, a newer topical corticosteroid, has been shown to have scleral penetration in rabbit models and may be a useful therapeutic agent in scleritis, but clinical data on its use in human scleritis are lacking.<sup>24</sup>

Oral NSAIDs should be considered the first line of treatment in patients with mild and moderately severe scleritis. They have been reported to be effective in diffuse scleritis and mild nodular scleritis.<sup>25</sup> Indomethacin 50 mg three times a day or, in the sustained-release form, 75 mg twice a day, can be very effective. Other nonsteroidal agents that appear to work well are piroxicam and naprosyn. Ibuprofen, diclofenac, tolmetin, sulindac, and others also may be of benefit.

All systemic nonsteroidal agents carry the risk of significant side effects. Long-term therapy may result in allergic reactions, GI problems, and kidney damage. An increased risk of cardiac events has been reported with both cyclooxygenase-2 (COX-2)-specific and COX-2-nonspecific NSAIDs. These medications should be avoided in those patients with significant cardiac risk factors, especially in patients with prior myocardial infarction, prior stroke, or recent cardiac arrhythmias.<sup>26</sup> Patients who take NSAIDs may require other medications to prevent or treat GI side effects. Options include histamine 2 (H<sub>2</sub>) receptor antagonists (e.g., ranitidine, famotidine, cimetidine), coating agents (e.g., sucralfate), gastric acid secretion inhibitors (e.g., the synthetic prostaglandin E<sub>1</sub> analogue misoprostol), and proton pump inhibitors (e.g., omeprazole). The NSAIDs that are selective COX-2 inhibitors may have fewer GI side effects but appear to be less potent anti-inflammatory agents.

Systemic corticosteroids often are used as initial therapy for patients with moderate to severe scleritis. The usual starting dose is 1 mg/kg/day of prednisone, but in severe cases, doses up to 1.5 mg/kg/day or even intravenous pulse corticosteroids may be required. The prednisone is then slowly tapered to a best-tolerated dose. Many patients require therapy for 6 months to a year or longer. Patients who require more than 3 months of treatment or 5 mg of chronic daily prednisone should be considered for corticosteroid-sparing agents. Occasionally, patients who take their full dose of oral prednisone in the morning experience pain at night. If the dose is divided and taken twice a day, this night pain may be relieved without increasing the total dose.

Pulse intravenous methylprednisolone at 0.5–1 g may be required in some patients with severe scleritis. This high dose may be used once a day for 3 days or once every other day for three doses and then reduced to once a week. Oral prednisone is often required to supplement the pulses.<sup>27</sup>

All systemic corticosteroids may result in adrenal suppression, weight gain, mood changes, blood pressure elevation, blood sugar elevation, osteoporosis, and aseptic necrosis of the femoral head. Any patient who is on oral prednisone for longer than 1 year, even on an every-other-day schedule, should have a bone density evaluation.

Subconjunctival injection has been proposed as a method of corticosteroid delivery in cases of nonnecrotizing anterior scleritis.<sup>28</sup> Its use typically is limited to adjunctive therapy in cases of nonnecrotizing localized disease, cognizant of the at least theoretical risk of scleral thinning and perforation.

Immunosuppressive or immunomodulatory therapy may be required in patients with scleritis who are unresponsive to or intolerant of prednisone, or who require long-term therapy (see Fig. 4.11.5). In patients with severe rheumatoid arthritis and GPA, morbidity and mortality are reduced with the use of immunosuppressive agents.<sup>29</sup> Many patients with necrotizing scleritis require immunosuppressive therapy to preserve vision. Evidence exists that well-managed immunosuppressives have less long-term toxicity compared with high- or moderate-dose prednisone.<sup>30</sup> All immunomodulatory therapy for scleritis is used off label.

Oral or subcutaneous methotrexate (7.5–25 mg weekly) has been reported to be of benefit in reducing or eliminating the need for systemic corticosteroid therapy.<sup>31</sup> Azathioprine at a dose of 1.5–2 mg/kg/day also may reduce or eliminate the need for corticosteroids.<sup>25,30</sup> However, both these agents can result in hepatic and hematological toxicity. Mycophenolate mofetil, another antimetabolite drug, may have lower toxicity and higher efficacy.<sup>32</sup>

Cyclosporine, which acts in part by interfering with interleukin-2, has been used with some success in the treatment of scleritis.<sup>30</sup> At doses of 10 mg/kg/day, it is nephrotoxic, so it is almost always used at lower doses,

**Fig. 4.11.8 Fluorescein Angiography.** (A) Fundus photograph demonstrating exudative retinal detachment and choroidal folds in posterior scleritis. (B) The same eye shows choroidal folds and areas of subretinal leakage, which increase in intensity in the late phases of the angiogram. Only Vogt-Koyanagi-Harada syndrome and posterior scleritis exhibit this subretinal leakage pattern. Many patients with posterior scleritis do not have this leakage pattern, however.

such as 5 mg/kg/day as an initial dose and 3–5 mg/kg/day as a maintenance dose. However, at these doses, it may be impossible to discontinue the use of corticosteroids. As such, cyclosporine is used as an adjunctive therapy, permitting lower doses of systemic corticosteroids, or in combination with other agents such as antimetabolites.<sup>33,34</sup> Systemic hypertension, renal failure, hirsutism, and gingival hyperplasia all may occur with cyclosporine. Tacrolimus (FK-506) has a different structure from that of cyclosporine but has similar intracellular actions and is supplied in a topical ointment that has been shown to be effective in a small number of scleritis cases.<sup>35</sup>

Biological medications have been shown to be particularly effective in treating scleritis. Tumor necrosis factor inhibitors, which include infliximab, adalimumab, etanercept, certolizumab, and golimumab, typically act rapidly in controlling inflammation. The majority of data in uveitis and scleritis are for infliximab and adalimumab. Although adalimumab recently received U.S. Food and Drug Administration approval for the treatment of noninfectious intermediate, posterior, and panuveitis in adults, its use in scleritis is still off label. In addition, rituximab has been shown to have excellent efficacy in refractory cases of scleritis.<sup>36</sup>

**Fig. 4.11.9 Ring Corneal Ulcer in a Patient With Rheumatoid Arthritis and Scleritis.** (A) Note the white, creamy infiltrates in the cornea, indicating active inflammation, and the lack of a lucid interval between the limbus to the ulcer. (B) Other eye of the same patient. Note the scarring and vascularization from a previously active ring ulcer.

**Fig. 4.11.10 Diffuse Scleritis Active Nasally.** Note the active sclerosing keratitis nasally and chronic changes from prior sclerosing keratitis temporally. The temporal scleritis has completely resolved.

These agents are usually prescribed and monitored in conjunction with a rheumatologist.

Alkylating agents, such as chlorambucil and cyclophosphamide, may be of benefit and usually enable oral prednisone to be tapered or discontinued.<sup>37,38</sup> In some cases, a 3- to 6-month course of chlorambucil, with

**Fig. 4.11.11 Subretinal Mass Mimicking an Amelanotic Melanoma in a Patient With Scleritis.** In this patient, the mass disappeared with cyclophosphamide therapy.

**Fig. 4.11.12 Patient With Relapsing Polychondritis.** Note inflammation of the superior half of the pinna.

reduction of the white blood cell count to 2400–3500, results in prolonged remission of ocular inflammatory disease.<sup>37,38</sup> Alkylating agents may have hematological toxicity, and blood counts must be monitored frequently. Cyclophosphamide has the added risk of hemorrhagic cystitis, so adequate hydration is imperative. Cyclophosphamide works more rapidly (frequently within a few days to a week) compared with chlorambucil. Pulse intravenous cyclophosphamide also has been used in severe sight- or life-threatening disease. Because alkylating agent use may increase the risk of late malignancy and sterility, detailed informed consent should be obtained before starting therapy. These agents may result in premature gonadal failure in males and females and are also teratogenic, so patients must be counseled carefully.

### Surgical Treatment

Surgery for scleritis may be performed when scleral perforation or extensive thinning exists with significant risk for scleral rupture. However, most patients who have thin sclera and even staphyloma formation do not require structural reinforcement. If the decision is made to reinforce the sclera, available agents include fresh or preserved donor sclera, periotum, or fascia lata. Donor sclera is relatively easy to use, but after several months, it may start to dissolve, as did the originally diseased tissue. Autologous periosteum can be harvested from the tibial crest and may be a better agent to use, as it may be less likely to necrose compared with donor sclera.<sup>39</sup>

**Fig. 4.11.13 Necrotizing Anterior Scleritis Secondary to Herpes Zoster.** The patient underwent extracapsular cataract extraction 2 weeks earlier, which precipitated ophthalmic zoster.

**Fig. 4.11.14 Necrotizing Scleritis Induced by Trabeculectomy Surgery.** Note the large conjunctival vessels seen in this 75-year-old woman; these are frequently seen after severe scleritis.

Many patients who have scleritis develop cataracts. Surgery for cataracts in such patients should be undertaken only when the disease has been in remission for at least 3 months. The physician should be alert to recognize recrudescence of scleral inflammation after surgery.

### Course and Outcome

Most patients with mild or moderate scleritis maintain excellent vision. The length of time during which scleritis is active varies from patient to patient. In a minority of patients, the disease is active for months and then goes into long-term remission. In other patients, the disease is active for several years. In some patients, the disease seems to move from eye to eye or to move from one area of sclera to another.

Necrotizing scleritis portends a worse prognosis compared with non-necrotizing disease. Patients with necrotizing scleritis have a high incidence of visual loss and a 21% 8-year mortality.<sup>14,40</sup> Immunosuppressive therapy appears to lessen these risks.

## Bacterial Keratitis

Jeremy D. Keenan, Stephen D. McLeod

4.12

**Definition:** Corneal disease caused by bacterial organisms.**Key Feature**

- Cellular infiltration of the corneal epithelium or stroma, corneal inflammation, and necrosis.

**Associated Features**

- Lid edema.
- Conjunctival inflammation.
- Discharge.
- Anterior chamber reaction.
- Hypopyon.

**INTRODUCTION**

Infectious keratitis is one of the leading causes of blindness in the world. Because, in most cases, these infections represent preventable or treatable ophthalmic diseases, a thorough understanding of the epidemiology, diagnosis, and treatment of the various forms of infectious keratitis is essential for eye-care practitioners and public health officials.

**EPIDEMIOLOGY AND PATHOGENESIS**

The estimated incidence of ulcerative keratitis in the United States is 28 per 100 000 person years, with a higher incidence among contact lens wearers (130 per 100 000 person years).<sup>1</sup> The incidence of infectious keratitis in the developing world is even higher, with estimated incidence rates ranging from 100 to 800 per 100 000 person years.<sup>2</sup> Given the potential blinding complications of severe bacterial keratitis, these infections are a significant public health issue.<sup>3</sup> A host of bacterial organisms can cause infectious keratitis. The incidence of infection by specific organisms varies by region. Practitioners should be aware of the local epidemiological patterns of corneal infection. Whereas staphylococcal species are most commonly seen in Canada and the eastern and northeastern United States, *Pseudomonas* infection is more common in the southern United States. *Streptococcus pneumoniae* was once the most common pathogen isolated from bacterial corneal ulcers, but as contact lens wear and related infectious keratitis have increased, the relative incidence of pseudomonal and staphylococcal infection has increased. These two organisms account for the majority of infections associated with contact lens wear, followed by *Serratia marcescens*. Corneal infections that occur in patients with systemic debilitating conditions, such as alcohol abuse, malnutrition, or diabetes often are associated with *Moraxella*. In the developing world, streptococcal corneal infection remains the most common, followed by staphylococcal and pseudomonal keratitis.

The corneal surface is normally well protected by a variety of mechanisms.<sup>4</sup> The eyelids and eyelashes form a physical outer barrier to foreign material, and the blink reflex sweeps away debris trapped in tears. A second line of defense is the tear film, which contains a variety of antimicrobial and anti-inflammatory factors, such as lactoferrin, lysozyme, beta-lysin, tear-specific albumin, and immunoglobulin A (IgA). Finally, the corneal and conjunctival epithelial cells provide a barrier via their tight junctions, express molecules important for innate immunity (e.g., toll-like receptors), and produce a variety of antimicrobial peptides.

The conjunctiva provides additional protection from infection. The conjunctiva contains mast cells, which, when activated, induce vascular

dilatation and increased vascular permeability, which results in the production of an antimicrobial transudate. The conjunctiva also contains conjunctiva-associated lymphoid tissue (CALT), which consists of nodules of small and medium-sized lymphocytes responsible for local antigen processing. Plasma cells, macrophages, and a variety of T cells also are present, as well as IgG, IgA, and IgM, which are brought in by the conjunctival vasculature.

The natural microbial environment of the ocular surface consists of both sessile and free-floating bacteria. This population is kept in check by the antimicrobial features of the tear film, and by the products of resident microbes; these products, called *bacteriocins*, are high-molecular-weight proteins that inhibit the growth of pathogens, such as pneumococci and Gram-negative bacilli.

In the majority of cases where bacterial keratitis develops, at least one risk factor that represents a compromise of one or more of these defense mechanisms can be identified. In developed countries, soft contact lens wear is the most important risk factor. Contact lenses likely cause physiological and traumatic changes to the ocular surface, additionally providing a scaffold for bacterial biofilm formation.<sup>5,6</sup> Extended or overnight contact lens wear and poor lens hygiene substantially increase the risk; unfortunately, daily disposable lenses may not reduce this risk. Corneal trauma, as well as keratorefractive procedures, such as laser in situ keratomileusis (LASIK), can disrupt the epithelial barrier and allow invasion of infectious organisms into the stroma (Fig. 4.12.1).<sup>7</sup> Lid abnormalities, such as entropion or ectropion, exposure of the corneal surface, or trichiasis, can cause breakdown of the protective corneal epithelium. Poor tear production can lead to a reduction of antimicrobial tear components and epithelial desiccation and damage. Epithelial problems, such as bullous keratopathy, medication toxicity, and prior herpetic infection, can allow microbial adherence and invasion. Drugs that may be smoked, such as cocaine and methamphetamine, have been associated with microbial keratitis, probably because of a direct toxic effect, exposure keratopathy, neurotrophic changes, or mechanical trauma (Fig. 4.12.2). Local or systemic immune compromise can lead to impairment of local immune defenses. This is most commonly caused by the use of topical corticosteroids, but immunosuppression, malignancy, malnutrition, or extensive burns also can cause it. Occasionally, keratitis can be established via the corneoscleral limbus by hematogenous spread.

**CLINICAL FEATURES**

The clinical signs and symptoms of bacterial keratitis depend greatly on the virulence of the organism and the duration of infection. Other influential factors include the previous status of the cornea and the use of corticosteroids. Patients may describe decreased vision, pain, and photophobia. The cardinal corneal sign is a localized or diffuse infiltration of the epithelium or stroma (Fig. 4.12.3). Commonly, epithelial absence over a gray-white necrotic stromal infiltrate occurs. Less commonly, a stromal abscess can appear beneath an intact epithelium. Infiltration and edema of the cornea can appear distant to the primary site of infection. Occasionally, bacterial keratitis can present with predominantly multifocal epithelial infiltration, especially in the setting of soft contact lens wear.

Other ocular structures usually demonstrate associated inflammation. Some degree of lid erythema and edema, conjunctival injection and chemosis, tearing, and discharge often occur. A nonspecific conjunctival papillary response might be seen. Anterior chamber inflammation often is present, ranging from cells and flare in milder cases to hypopyon in more severe cases. The aqueous might become dense and fibrinoid, and fibrinous endothelial plaques may develop. The hypopyon usually is sterile unless accompanied by a full-thickness corneal perforation.

**Fig. 4.12.1 Keratitis.** (A) Severe keratitis caused by *Pseudomonas* following radial keratotomy. (B) Scarring at the interface of a LASIK flap and bed following *Aspergillus* keratitis.

**Fig. 4.12.2 Epithelial Defect, Stromal Infiltrate, and Hypopyon Associated With Crack Cocaine Use.** *Candida*, *Streptococcus*, and *Haemophilus* species were recovered from scrapings of the infiltrate.

## Gram-Positive Cocci

### Staphylococcus

Staphylococci are Gram-positive cocci, which, on stained smears, tend to appear singly or in pairs, although clusters of organisms can be seen. The two most common species that cause keratitis are *Staphylococcus aureus* and *Staphylococcus epidermidis*, both of which are commonly found on skin, eyelids, and the conjunctiva. Although non-*aureus* strains are usually less virulent, antibiotic resistance tends to be more common, and aggressive keratitis occasionally occurs.

**Fig. 4.12.3** Bacterial corneal infection with dense central necrotic ulcer and infiltrate.

**Fig. 4.12.4** Streptococcal bacterial keratitis with infiltration of the central cornea.

Infection tends to occur in compromised corneas, such as those with bullous keratopathy, herpetic disease, and persistent epithelial defect. Usually a well-defined, cream-colored or gray-white stromal infiltrate with an overlying epithelial defect is seen. Sometimes multiple foci of abscesses can develop that resemble fungal satellite lesions. *S. aureus* tends to cause more severe infiltration and necrosis than *S. epidermidis*. Over time, the former can extend deep into the stroma, and necrosis of this abscess can lead to perforation. A hypopyon and endothelial plaque can be seen.

### Streptococcus

Streptococci are Gram-positive cocci. On stained smears, most species tend to appear in chains, but they also can be arranged singly, in pairs, or in loose clusters. The most common species causing keratitis is *Streptococcus pneumoniae* (*Pneumococcus*), which appears as lancet-shaped diplococci arranged with the flattened ends together. Streptococcal species are distinguished by their ability to hemolyze red blood cells. *Streptococcus viridans* and *S. pneumoniae* do so partially (alpha-hemolysis), *S. pyogenes* completely (beta hemolysis), and gamma-hemolytic species do not hemolyze red blood cells at all.

Pneumococcal infections can readily spread, producing a deep stromal abscess, fibrin deposition, plaque formation, severe anterior chamber reaction, hypopyon, and iris synechiae (Fig. 4.12.4). The advancing necrosis often produces an undermined leading edge with overhanging tissue. Infection by *Streptococcus pyogenes* occurs less frequently but has a similar, severe presentation and course. Group viridans *Streptococcus* spp. tend to cause less aggressive disease and are associated with a more indolent course, as is seen in infectious crystalline keratopathy.

Infectious crystalline keratopathy describes a particular pattern of corneal infiltration characterized by needle-like opacities that can be found at all levels of the corneal stroma (Fig. 4.12.5). The crystalline opacities range from fine, feathery, and white to thick, brown, arborizing aggregations, without apparent cellular infiltrate or ocular inflammation. The entity most frequently occurs in corneal grafts but has also been associated with

**Fig. 4.12.5** Infectious crystalline keratopathy caused by *Streptococcus viridans*.

**Fig. 4.12.6** Serrated border and satellite lesions in keratitis caused by *Nocardia*.

other conditions, such as incisional keratotomy, epikeratophakia, contact lens wear, chemical burns, and topical anesthetic abuse. Long-term corticosteroid therapy is thought to play a role in the pathogenesis. Although the viridans group of streptococci accounts for most cases, other organisms associated with infectious crystalline keratopathy include *S. pneumoniae*, *Haemophilus aphrophilus*, *Peptostreptococcus*, *Pseudomonas aeruginosa*, and a number of other bacteria, as well as *Candida* and *Alternaria* fungal species.

## Gram-Positive Bacilli

### Bacillus

*Bacillus cereus* is an aerobic, spore-forming, typically Gram-positive rod, although considerable variability in staining characteristics has been noted. They are ubiquitous and are found in water, in soil, and on vegetation. Corneal infection, therefore, can be seen after penetrating injury, especially when soil contamination occurs. *Bacillus* infection also has been reported in contact lens-related keratitis. Posttraumatic infection characteristically develops within 24 hours of injury and is associated with chemosis, profound lid edema, and proptosis. A diffuse or a peripheral ring of microcystic edema often occurs, followed by a circumferential corneal abscess. This is an extremely virulent organism, and perforation of the cornea can develop within hours.

### Corynebacterium

The corynebacteria, which include *C. diphtheriae*, are Gram-positive, club-shaped or pleomorphic rods arranged in the so-called Chinese-letter formation, Y's, or palisades. An infrequent cause of keratitis, the clinical picture characteristically begins with diffuse epithelial haze, followed by stromal necrosis and melting.

### Listeria

*Listeria monocytogenes* is a Gram-positive, short, rod-shaped facultative anaerobe. Infection usually occurs in animal handlers. It can colonize persistent epithelial defects and lead to a necrotizing keratitis. Typically, a ring ulcer and an exuberant anterior chamber reaction with fibrinous exudate and a hypopyon occur.

### Clostridium

Clostridia are anaerobic, spore-forming, Gram-positive bacilli. Infrequently, clostridial conjunctivitis can be associated with the development of a marginal keratitis. Direct corneal infection is associated with marked edema and a frothy, bullous keratitis caused by trapped intraepithelial, subepithelial, and intrastromal gas produced by the organism. Gas might also be seen in the anterior chamber.<sup>8</sup>

### Propionibacterium acnes

*Propionibacterium acnes* is an anaerobic, nonspore-forming, Gram-positive rod. It forms part of the normal flora of the eyelid and conjunctiva. Keratitis can be established in the setting of corneal disease, trauma, surgery, contact lens wear, or chronic topical corticosteroid use.<sup>9</sup> Although keratitis caused by *P. acnes* can assume the appearance of typical infectious

keratitis, the infection can be indolent, with a stromal abscess covered by an intact epithelium.

## Filamentous Bacteria

### Actinomyces and Nocardia

*Actinomyces* and *Nocardia* are Gram-positive, filamentous bacteria. *Actinomyces* is obligatorily anaerobic and nonacid-fast, whereas *Nocardia* is obligatorily aerobic and variably acid-fast. On Gram staining, the filaments of these organisms are seen as branching and intertwined; some might display terminal clubs, and the filaments often fragment into bacillary and coccoid forms.

Actinomycotic keratitis is usually part of a mixed infection with other organisms that might have different antibiotic sensitivities. Infection is rare and usually follows trauma. Typically, the ulcer bed appears dry and necrotic and is surrounded by a yellow demarcating gutter.<sup>10</sup> Alternatively, ring abscesses have been described. Inflammation can be severe, with iritis and a hypopyon.

Infections by *Nocardia* also tend to follow trauma, especially if soil contamination occurs. The ulcer is characteristically superficial, with a wreath-shaped gray-white infiltrate and an undermined necrotic edge (Fig. 4.12.6). The base might assume a cracked windshield appearance. *Nocardia* keratitis often resembles fungal infection, with a filamentous-appearing border and satellite lesions.

## Gram-Negative Rods

### Pseudomonas

*Pseudomonas aeruginosa* is the most common Gram-negative organism isolated from corneal ulcers and is a frequent cause of contact lens-associated keratitis. These aerobic bacilli are found in moist environments and frequently contaminate inadequately chlorinated swimming pools and hot tubs, ventilators, nebulizer and vaporizer solutions, and ophthalmic solution bottles. The organism readily adheres to damaged epithelium. Stromal invasion is rapid.

*Pseudomonas* keratitis tends to progress rapidly if inadequately treated. Most commonly, the organism produces destructive enzymes, such as protease, lipase, elastase, and exotoxin, which result in necrotic, soupy ulceration. The organism's surface glycocalyx protects it against phagocytosis and complement attack. The ulcer often extends peripherally and deeply within hours and rapidly can involve the entire cornea (Fig. 4.12.7). Ring ulcers can develop. The corneal epithelium peripheral to the primary ulcer typically develops a diffuse gray, ground-glass appearance. The corneal stroma appears to dissolve into a greenish-yellow mucous discharge that fluoresces under ultraviolet (but not under cobalt blue) light. The suppurative ulcer frequently thins to a descemetocoele that perforates. The ulcer often is associated with a marked anterior chamber reaction and hypopyon formation. Extensive keratitis can extend to the limbus and produce an infectious scleritis.

Less virulent strains follow a more indolent course. Multifocal epithelial infection also can be seen, with multiple intraepithelial gray-white nodules accompanied by a granular-appearing stromal infiltrate and anterior

**Fig. 4.12.7** Infection of the Cornea Caused by *Pseudomonas*. There is liquefying necrosis, advanced central thinning, and hypopyon formation.

**Fig. 4.12.8** Intraepithelial infiltration of the cornea by *Pseudomonas* in a hydrophilic contact lens wearer.

chamber inflammation (Fig. 4.12.8). Diffuse epithelial disease is most commonly seen in association with hydrophilic contact lens wear.

### Serratia

These Gram-negative rods are found in soil, water, food, and the gastrointestinal tract. Keratitis often occurs in association with hydrophilic contact lens wear. The infection may begin as a superficial central or paracentral ulcer that invades the deeper layers of the cornea, producing a deep, ring-shaped keratitis. Exotoxins and protease can produce aggressive ulceration and perforation. Contact lens-associated disease also can present with multiple gray intraepithelial nodules that assume a branching linear pattern, accompanied by a granular-appearing stromal infiltrate and anterior chamber inflammation.

### Escherichia, Klebsiella, and Proteus

Infection by this group of Gram-negative rods is associated with contact lens wear and diseased eyes. The features of corneal infection can be similar to those seen in a virulent pseudomonal infection, with aggressive necrosis, ring ulcer formation, and perforation. Alternatively, the keratitis might be less aggressive with indolent ulceration and a moderate anterior chamber reaction. Suppurative keratitis caused by *Escherichia coli* is typically more indolent but is usually accompanied by severe iridocyclitis and hypopyon formation.

### Moraxella

*Moraxella* species are large, Gram-negative (or Gram-variable) bacilli that are described as having a square “boxcar” shape. They are found in pairs and chains. Moraxella keratitis occurs most frequently in patients with alcoholism and debilitated patients. Marginal ulcers occur in association

with angular blepharoconjunctivitis characterized by a gray, ulcerated infiltrate separated from the limbus by a clear crescent. Central indolent ulcers also occur. These most often develop in the lower half of the cornea as a gray infiltrate that eventually forms an oval-shaped ulcer. The infection tends to extend deeply rather than peripherally and does so slowly. The anterior chamber reaction can be vigorous. Uncommonly, perforation can occur.

### Haemophilus

*Haemophilus influenzae* is a Gram-negative bacillus or coccobacillus that can cause conjunctivitis that leads to keratitis. Infrequently, keratitis has been associated with contact lens wear and chronic corneal disease. The infection usually is superficial but extensive; it can be suppurative and might be associated with a hypopyon.

### Gram-Negative Cocci

#### Neisseria

*Neisseria gonorrhoeae* and *N. meningitidis* are Gram-negative, intracellular diplococci. In corneal and conjunctival scrapings they are found within epithelial cells. In a newborn with ophthalmia neonatorum, gonorrheal conjunctivitis is a significant concern because the organism can invade through an intact epithelium. Corneal infection often is peripheral and can progress to perforation and endophthalmitis. In adults, ocular gonorrhea is accompanied by a copious weeping, hyperpurulent discharge. Keratitis most commonly occurs after prolonged conjunctivitis. The transient, usually peripheral subepithelial infiltrates that might be seen likely represent a type III hypersensitivity reaction. Keratitis is characterized by diffuse edema or a ring ulcer with hypopyon. A significant risk of corneal necrosis and perforation exists.

Meningococcal conjunctivitis also can be complicated by keratitis, although this is less common than with gonococcal conjunctivitis. Typically, the keratitis is multifocal, and a peripheral infiltrate progresses to ulceration.

#### Moraxella (Branhamella) catarrhalis

*Moraxella catarrhalis* is a Gram-negative diplococcus that resembles *N. gonorrhoeae*. However, on smears of the conjunctiva, it is not found within epithelial cells. It can be a constituent of the normal flora of the conjunctiva and is an opportunistic pathogen. Although it can be associated with both neonatal and adult conjunctivitis, it is an infrequent cause of keratitis.

### Mycobacteria

#### Nontuberculous Mycobacteria

Of this group of organisms, the *Mycobacterium abscessus/chelonae* complex and *M. fortuitum* are most commonly associated with ocular disease, although *M. avium-intracellulare* and *M. gordonae* also have been reported to cause infectious keratitis.<sup>11,12</sup> These long rods are acid-fast; that is, they retain red basic fuchsin dye with Ziehl–Neelsen staining. Nontuberculous mycobacteria can grow in disinfectant and are found free in the environment, including soil. Keratitis most commonly follows trauma or surgery and has been associated with penetrating keratoplasty and refractive surgery. These corneal ulcers tend to be indolent and have been confused with mycotic keratitis. The infiltrated base of this typically nonsuppurative ulcer characteristically assumes a “cracked windshield” appearance, with multiple radiating lines. Satellite lesions, immune ring, and endothelial plaque formation might develop as the infection progresses.

### DIAGNOSIS

The presumptive diagnosis of infectious keratitis is based primarily on clinical history and physical examination, but confirmation of infectious infiltration and definitive identification of the offending organism can be achieved only by examining stained smears of corneal scrapings and laboratory cultures of these scrapings. In practice, specific identification of the offending organism and antibiotic sensitivity data are necessary only if they can guide modification of antibiotic treatment if the initial antibiotic regimen fails. Approximately 95% of suspected bacterial ulcers respond favorably to a well-chosen initial antibiotic regimen, so treatment modification rarely is necessary.<sup>13,14</sup> Many practitioners, therefore, defer diagnostic stains and cultures for selected cases of suspected bacterial keratitis. Some evidence exists that small infiltrates that are not associated with advanced suppuration or severe intraocular inflammation respond favorably to this approach.<sup>14</sup> Scrapings are mandatory if the infection is advanced or central

TABLE 4.12.1 Common Culture Media		
Medium	Organism	Comment
Blood agar	Aerobic bacteria Saprophytic fungi	37 °C for bacteria Room temperature for fungi
Chocolate agar	<i>Haemophilus</i> , <i>Neisseria</i> , <i>Moraxella</i>	5%–10% carbon dioxide
Brain–heart infusion (BHI)	Bacteria Fungi	
Sabouraud’s dextrose agar	Fungi	Room temperature
Enriched thioglycollate broth	Aerobic and anaerobic bacteria	Good for small inocula but prone to contamination
Löwenstein–Jensen agar	Nontuberculous mycobacteria	
<i>Escherichia coli</i> plated nonnutrient agar	<i>Acanthamoeba</i>	Transport sample to plate in Page’s saline

TABLE 4.12.2 Stains for Smears and Corneal Scrapings		
Stain	Organism	Comment
Gram	Bacteria, fungi, <i>Acanthamoeba</i> , microsporidia	Stains walls of fungi
Giemsa	Bacteria, fungi, chlamydial inclusions, <i>Acanthamoeba</i> , microsporidia	All stain blue; does not demonstrate intranuclear inclusions; stains fungal cytoplasm
Gomori’s methenamine silver (GMS)	Fungi	Difficult technique
Ink–potassium hydroxide	Fungi	Displays fungal walls
Periodic acid–Schiff (PAS)	Fungi	
Acridine orange	Bacteria, fungi, <i>Acanthamoeba</i>	Requires fluorescent microscope
Calcofluor white	Fungi, <i>Acanthamoeba</i>	Requires fluorescent microscope
Weber	Microsporidia	
Ziehl–Neelsen	Mycobacteria, <i>Nocardia</i> , <i>Actinomyces</i>	

or if history or examination is at all suggestive of filamentous bacterial, nontuberculous mycobacterial, gonococcal, mycotic, or protozoal infection.

When scrapings of corneal ulcers are obtained, material should be taken from the most active regions. The eye is anesthetized with topical anesthetic, and a heat-sterilized platinum spatula or blade is used to firmly scrape the leading edges of the ulcer. Multiple areas of a large ulcer should be sampled. If significant corneal thinning is evident, care must be exercised not to precipitate perforation. Some investigators have reported acceptable organism recovery rates with scrapings performed with a calcium alginate swab moistened with soy broth.<sup>15</sup> Scrapings should be placed on a slide for staining and directly applied to culture media to maximize the chance of recovery.

Commonly used culture media are described in Table 4.12.1. Multiple C-streaks should be used on agar plates because it is often difficult to identify an organism recovered in culture as the offending pathogen, and growth outside of the C-streak might indicate contamination. The most commonly applied stains are Gram and Giemsa stains (Table 4.12.2). Gram stain is useful to identify bacteria and yeasts. Giemsa stain is useful for cytology and to identify bacteria (all stain blue), fungi, and chlamydial inclusions. If filamentous bacterial or nontuberculous mycobacterial infection is suspected, Ziehl–Neelsen staining should be performed. Molecular diagnosis of bacterial keratitis is possible with polymerase chain reaction assays targeting 16S ribosomal RNA; however, this approach is limited by false positives, presumably from normal ocular surface flora.<sup>16</sup>

Corneal biopsy is indicated when an apparent infection fails to resolve in spite of antimicrobial treatment, when the identity of the organism is in doubt or when conventional scrapings have failed to demonstrate a reasonably culpable organism.<sup>17</sup> Corneal stromal biopsy is sometimes necessary to identify protozoan, mycobacterial, or mycotic organisms. As with corneal scrapings, the corneal biopsy specimen should incorporate the active edge and base of the ulcer. If the infiltrate is sequestered within the stroma, a lamellar technique is required. Tissue obtained through biopsy should be sectioned, with a portion submitted to the pathologist for microscopic examination, and a portion used for direct inoculation of plates and broth for culture and sensitivity studies.

BOX 4.12.1 Differential Diagnosis of Corneal Infiltration and Ulceration

- Infectious**
  - Bacteria
  - Fungi
  - Parasites
    - *Acanthamoeba*
    - *Microsporidiosis*

  - Smokable drug–induced
  - Anesthetic abuse
  - Xerophthalmia, keratomalacia

DIFFERENTIAL DIAGNOSIS

See Box 4.12.1.

SYSTEMIC ASSOCIATIONS

Mechanisms that protect the cornea from infection involve both mechanical and immunological strategies. Systemic conditions that affect the mechanical protective function of the lids as a result of lagophthalmos or reduced blinking include chronic alcoholism, dementia, parkinsonism, general anesthesia, and coma. Bullous conditions that affect both skin and eye, such as erythema multiforme and ocular cicatricial pemphigoid, are associated with an increased risk of infectious keratitis not only because of lagophthalmos but also because of inflammatory cicatricial conjunctival changes. Patients with human immunodeficiency virus infection are more likely to develop infectious keratitis and have a more fulminant presentation, presumably as a result of impaired local immune defenses.<sup>1,18</sup> Malnutrition and conditions caused by vitamin deficiency, such as xerophthalmia and scurvy, appear to increase the risk of posttraumatic infection.

PATHOLOGY

Histopathologically, bacterial keratitis is characterized by inflammation, necrosis, and angiogenesis. Bacteria and host each contribute to the inflammatory response. Although virulence factors are specific to each organism, bacteria generally produce a variety of toxins and proteases that result in degradation of connective tissue and host defense factors, and necrosis.<sup>19</sup> Corneal infection results in recruitment of inflammatory cells, with a predominance of polymorphonuclear leukocytes (PMNs) that arrive initially via the tear film and later via proliferating limbal blood vessels. PMNs not only phagocytize bacteria and necrotic stroma but also release lysosomal enzymes that contribute to stromal necrosis and corneal thinning. If the bacterial population overwhelms the cornea’s protective mechanisms or if the necrosis progresses unchecked, corneal perforation and possibly endophthalmitis will result. However, if the infection is brought under control, the infiltrate will decrease in size and the epithelium will heal over the ulcer. Scar tissue is produced by activated keratocytes and transformed histiocytes. Angiogenesis might be stimulated by the inflammation, but these vessels usually regress with time.

TREATMENT

Infectious keratitis should be considered an ocular emergency. Antibiotic therapy must be initiated promptly.<sup>20</sup> Topical administration is the route of choice because it provides rapid, high levels of drug in the cornea and anterior chamber (Table 4.12.3). Subconjunctival injection may be helpful in cases with scleral spread or in patients unable to instill frequent eyedrops. Systemic administration results in relatively low antibiotic levels in the cornea and is generally advised only when keratitis is complicated by scleritis or a risk of perforation or endophthalmitis exists.<sup>21</sup> Antibiotic-soaked collagen shields enhance topical delivery in animal models, but the clinical usefulness of this method has not been established.<sup>22</sup> Severe or central ulcers are typically treated with a loading dose (e.g., every 5–15 minutes for the first hour) followed by application every 30–60 minutes. If a combination of two antibiotics is prescribed, the drops

TABLE 4.12.3 Commonly Used Antibiotics for the Treatment of Bacterial Keratitis

Antibiotic	Concentration	Route	Activity
<b>Aminoglycosides</b>			Gram-negatives, staphylococci, some streptococci (not pneumococcus)
Amikacin	20–50 mg/mL 50 mg/mL	Topical Subconjunctival	Also active against nontuberculous mycobacteria
Gentamicin	14 mg/mL 40 mg/mL	Topical Subconjunctival	
Tobramycin	14 mg/mL 40 mg/mL	Topical Subconjunctival	
<b>Cephalosporins</b>			Active against Gram-positive organisms and some Gram-negative bacilli
Cefazolin	50–100 mg/mL 200 mg/mL	Topical Subconjunctival	
<b>Fluoroquinolones</b>			Active against Gram-negatives, fair to good against Gram-positives
Besifloxacin	6 mg/mL	Topical	
Ciprofloxacin	3 mg/mL	Topical	
Gatifloxacin	3 mg/mL	Topical	
Levofloxacin	5–15 mg/mL	Topical	
Moxifloxacin	5 mg/mL	Topical	
Ofloxacin	3 mg/mL	Topical	
<b>Penicillins</b>			
Penicillin G	100 000 U/mL 1 000 000 U/mL	Topical Subconjunctival	Active against nonpenicillinase-producing Gram-positive organisms
Methicillin	50 mg/mL 200 mg/mL	Topical Subconjunctival	Active against penicillinase-producing Gram-positive organisms
Piperacillin	7 mg/mL 200 mg/mL	Topical Subconjunctival	Active against Gram-positives and some Gram-negatives, including <i>Pseudomonas</i>
<b>Vancomycin</b>	33 mg/mL 100 mg/mL	Topical Subconjunctival	Active against Gram-positive organisms, including methicillin-resistant staphylococci

are given in an alternating fashion. Subsequent reductions are dictated by the response of the infection.

Initially, empirical topical therapy should be instituted with a broad-spectrum antibiotic regimen.<sup>23</sup> The most commonly used regimens include fluoroquinolone monotherapy or combination therapy with a cephalosporin and aminoglycoside; these two regimens are thought to have similar efficacy in most cases, with approximately 90% of cases responding to therapy (see Table 4.12.3).<sup>13,24</sup>

Fluoroquinolone antibiotics demonstrate excellent activity against Gram-negative organisms and good to excellent activity against Gram-positive organisms. Of the commercially available ophthalmic fluoroquinolones, the newer agents (levofloxacin, moxifloxacin, gatifloxacin, and besifloxacin) offer enhanced Gram-positive coverage compared with the older agents (ofloxacin and ciprofloxacin).<sup>25</sup> Ciprofloxacin remains the fluoroquinolone of choice for *P. aeruginosa*. Although fluoroquinolone monotherapy is thought to be effective in most cases, emerging resistance has been noted for several organisms responsible for infectious keratitis, including *P. aeruginosa* and *S. aureus*.<sup>26,27</sup> Therefore, fluoroquinolone monotherapy should be applied with great caution and with careful observation for a clinical response.

The aminoglycosides most commonly used for the treatment of infectious keratitis are gentamicin and tobramycin. Both are prepared at a “fortified” concentration of 9–20 mg/mL. These antibiotics provide excellent Gram-negative coverage and also are active against staphylococci and some streptococci but not against pneumococci. Tobramycin may be more active than gentamicin against *P. aeruginosa*.<sup>28</sup> Amikacin is a semisynthetic aminoglycoside that is useful in the treatment of Gram-negative organisms resistant to gentamicin and tobramycin, as well as nontuberculous mycobacterial organisms. Because infectious keratitis following refractive surgery often is caused by mycobacteria, amikacin may be given empirically in this situation.<sup>29</sup> Aminoglycosides tend to inhibit epithelial wound healing and can cause a punctate epitheliopathy.

The cephalosporins are a class of beta-lactam antibiotics with efficacy against Gram-positive organisms and some Gram-negative bacilli, such as *E. coli*, *Klebsiella*, and *P. mirabilis*. Cefazolin, a first-generation cephalosporin, is relatively nontoxic to the corneal epithelium, and the agent most commonly used for treatment of infectious keratitis. A third-generation agent, ceftazidime, has efficacy against *P. aeruginosa* and is an option for resistant cases.

The penicillins are effective against many Gram-positive organisms, such as streptococcal and staphylococcal species, as well as gonococcal and some anaerobic species. However, many staphylococcal strains produce beta-lactamase, which inactivates penicillin. Moreover, approximately 10% of patients have an allergic reaction to penicillins. The penicillin and penicillin-derived antibiotics can be administered both topically and subconjunctivally.

Vancomycin is a useful agent against staphylococcal organisms when cephalosporins are ineffective or poorly tolerated. Vancomycin is a glycopeptide antibiotic with activity against methicillin-resistant staphylococci and other Gram-positive organisms. However, to minimize the development of resistance, empirical therapy should be used judiciously.<sup>30</sup>

Empiric therapy may need to be altered depending on the results of microbiological tests. Keratitis caused by *Neisseria gonorrhoeae* should be treated systemically with a single dose of intramuscular ceftriaxone, and the patient should be given systemic azithromycin or doxycycline for possible chlamydial co-infection.<sup>31</sup> In addition, patients with gonococcal keratitis should have the conjunctival sac irrigated frequently with normal saline, followed by topical administration of a fluoroquinolone antibiotic solution. Keratitis caused by *N. meningitidis* should prompt empiric therapy with a third-generation cephalosporin, which can be changed to penicillin depending on the results of susceptibility testing. Actinomyces infections generally have poor in vitro susceptibility to aminoglycosides and fluoroquinolones, and usually are treated with topical sulfacetamide or penicillin, as well as with subconjunctival penicillin. Nocardia keratitis is typically treated topically with amikacin or a sulfonamide, and oral trimethoprim and sulfamethoxazole for cases that progress on topical therapy.<sup>32</sup> Nontuberculous mycobacterial keratitis has been successfully treated with fluoroquinolone antibiotics, although in general the susceptibilities of amikacin and clarithromycin are superior to those of the fluoroquinolones.<sup>12</sup> Prolonged therapy of these recalcitrant mycobacterial infections often is needed, and in certain cases, lamellar or penetrating keratoplasty might be necessary.

If antibiotic susceptibility testing is available, these data can be used as a relative guide in choosing antibiotics that might have a higher probability of eradicating the offending microbe. Antibiotic sensitivities are most commonly measured by disc diffusion or serial dilution methods. These tests typically report the susceptibility of the bacterial isolate to each tested drug based on the minimum inhibitory concentration (MIC), which is the lowest concentration of antibiotic that inhibits bacterial growth. However, it is important to recognize that most laboratories base the definition of resistance on MIC thresholds that have been established for the expected serum concentration of the antibiotic. With frequent ophthalmic application of a topical antibiotic preparation, relatively high corneal concentrations of many antibiotics can be established; therefore, organisms cultured from a corneal infiltrate may be reported as “resistant” to a particular antibiotic but respond to treatment because of the effect of high local concentration.<sup>33</sup> Nonetheless, higher MICs are associated with larger corneal scars and worse visual acuity, which suggests that tailoring therapy based on MIC may be of benefit.<sup>34</sup>

If a single antibiotic is chosen initially and is effective in treating the infection, there is seldom a reason to change therapy. If a combination of antibiotics is initially effective, administration of the less effective (by susceptibility studies) of the two often can be halted after a few days. Fortified preparations can be replaced by commercial preparations, and the frequency of application can be gradually tapered. Treatment should be continued at least until the epithelium has completely healed. *Pseudomonas aeruginosa* can reappear after apparent resolution if treatment is halted early; antibiotic administration should be maintained for at least a week after epithelial healing.

The initial sign of effective treatment is failure of the infiltrate to worsen; however, it is not uncommon for ulcers to initially worsen before stabilizing, even with an effective initial antibiotic regimen. The early signs of a resolving infection include stabilization of the area and depth of the infiltrate and reduced activity at the infiltrate’s margins. Signs of continuing improvement include progressive healing of the epithelial defect, clearing of the infiltrate, reduced corneal edema adjacent to the infiltrate, and decreasing inflammation and anterior chamber reaction. It is important to

note that corneal stromal necrosis might progress in spite of effective antimicrobial treatment because of the lytic activity of immigrant leukocytes. In addition, immunological ring infiltrates can appear many days after the initiation of effective antimicrobial treatment and might be erroneously interpreted to indicate worsening of the infection.

If the corneal ulcer fails to improve, corneal scraping should be performed (or repeated) for smear and culture. In the case of indolent infections, antibiotic treatment might be interrupted for 24–48 hours to decrease the inhibitory effect of antibiotic treatment and, thus, increase the probability of recovering the organism. If no organism is recovered in bacterial culture and the disease worsens, noninfectious and nonbacterial causes of ulcerative keratitis must be considered (see Box 4.12.1). Appropriate cultures for nontuberculous mycobacteria, fungi, and protozoal organisms should be obtained. If repeat cultures are negative and the ulcer does not improve, corneal biopsy might be necessary. When obtaining corneal biopsy, the specimen should be sent for both microbiological and histopathological evaluation.<sup>17</sup>

Besides antimicrobial therapy, adjunctive treatments have been employed in an effort to minimize the adverse sequelae of corneal infection, such as perforation, vascularization, and scarring. Corticosteroids can be used to suppress the inflammatory response that leads to these adverse sequelae. Corticosteroids reduce the host inflammatory response, thereby improving patient comfort and theoretically resulting in less stromal scarring. However, corticosteroids also have been shown to delay re-epithelization of corneal ulcers, and if antibiotic therapy is inadequate, to promote bacterial replication.<sup>35</sup> The Steroids for Corneal Ulcers Trial (SCUT) was a randomized placebo-controlled trial that found that topical corticosteroid therapy started after at least 48 hours of antibiotics did not significantly improve visual acuity at 3 months, although corticosteroids were associated with improved vision in the most severe ulcers.<sup>36</sup> The rate of corneal perforation was similar in the two treatment groups. Subgroup analyses produced similar findings for pseudomonal ulcers, but not for *Nocardia* ulcers, which had significantly worse outcomes with corticosteroid treatment.<sup>37,38</sup> A secondary analysis of SCUT found that corticosteroids significantly improved 3-month visual acuity if started within 3 days of initiating antibiotic therapy, but had no effect if the delay was 4 days or later.<sup>39</sup> This suggests that corticosteroids may be safely used for non-*Nocardia* bacterial keratitis to reduce pain and inflammation and that severe ulcers given prompt corticosteroid therapy may even have a benefit in visual outcomes. However, corticosteroids should not be used if there is any suspicion of fungal or amoebic keratitis, or if doubt exists about the efficacy of the antimicrobial regimen. Nonsteroidal anti-inflammatory agents might help reduce the adverse sequelae of infectious inflammation, but, again, they should be used only in the presence of effective antimicrobial treatment.<sup>40</sup> Cycloplegic agents are useful in reducing discomfort caused by ciliary body spasm and can be used periodically to decrease synechiae formation. Finally, *in vitro* studies have suggested that stromal necrosis may be prevented by several potential collagenase inhibitors, including acetylcysteine, citrate, and doxycycline.<sup>41</sup> The clinical utility of these collagenase inhibitors, however, remains unclear.

Surgical intervention is warranted when necrosis progresses to perforation or impending perforation and may be considered for corneal ulcers that are unresponsive to medical therapy. For small perforations without extensive surrounding necrosis, cyanoacrylate glue can be applied (Fig. 4.12.9). Small perforations also have been successfully managed with fibrin glue and multilayered amniotic membrane grafts.<sup>42</sup> If the perforation is large or necrosis is extensive, corneal transplantation might be necessary. The choice between a small-diameter patch graft and a large-diameter graft and between a penetrating procedure and a lamellar procedure depends on the size, depth, and location of the ulcer. Deep anterior lamellar keratoplasty is an option for corneas that have not yet perforated; this technique may reduce the risk of graft failure and appears to have similar rates of disease recurrence compared with penetrating keratoplasty.<sup>43</sup> Therapeutic keratoplasty can result in favorable surgical outcomes, although the procedure can be complicated by the difficulties involved in operating on a perforated globe, concurrent infection, and inflammation that threatens graft success. Conjunctival flaps can be used to treat infections that fail to improve with medical therapy; this strategy might be especially useful in peripheral infectious ulceration. The vascularized conjunctival tissue helps admit blood vessels that aid in healing and scarring. Conjunctival flaps should not be placed over a corneal perforation.

**Fig. 4.12.9** Bacterial infection leading to central necrosis, thinning, and perforation, sealed with cyanoacrylate tissue adhesive.

## OUTCOME

The visual outcomes of bacterial keratitis vary greatly. In general, the most important predictor of final visual outcome is the visual acuity at diagnosis; patients with worse vision at diagnosis will have worse vision after the ulcer has healed.<sup>44</sup> Relatively small infiltrates that do not involve the central cornea might leave stromal scarring that is only faintly discerned on slit-lamp microscopy and has no visual consequence; more extensive ulceration and infiltration can result in significant scarring and irregular astigmatism. Residual scarring is thought to cause vision loss by blocking light, causing light scatter, and/or inducing irregular astigmatism. Persistent anterior stromal scars can sometimes be removed by excimer laser phototherapeutic keratectomy, but deeper scars require lamellar or penetrating keratoplasty. In the absence of significant opacification, irregular astigmatism is best treated with a rigid contact lens. Corneal inflammation can lead to neovascularization; these vessels may regress with time, and regression might be aided by corticosteroid therapy. Ocular inflammation also can lead to synechiae formation, elevated intraocular pressure, and cataract.

# Fungal Keratitis

Jeremy D. Keenan, Stephen D. McLeod

4.13

**Definition:** Corneal disease caused by fungal organisms.

## Key Feature

- Cellular infiltration of the corneal epithelium or stroma, corneal inflammation, and necrosis.

## Associated Features

- Long-term corticosteroid use.
- Trauma involving vegetative matter.
- Corneal infiltrate with feathery borders or satellite lesions.

## INTRODUCTION

Fungal infections of the cornea are relatively infrequent in the developed world but cause a large proportion of keratitis in many parts of the developing world. Although these infections can cause devastating damage if allowed to progress unchecked, advances in antimicrobial therapy and surgical technique have improved their prognosis. Recognition and prompt, aggressive therapy of fungal infections are extremely important.

## EPIDEMIOLOGY AND PATHOGENESIS

Fungi are ubiquitous organisms that are recognized more frequently as ocular pathogens in agrarian, tropical countries than in the developed world. For clinical purposes, fungi can be classified on a morphological basis into filamentous, yeast, and diphasic forms. Filamentous organisms are multicellular with branched hyphae. Septate filamentous organisms, such as *Fusarium* and *Aspergillus*, have hyphae that are divided by cell walls. Other filamentous fungi, including *Mucor* and *Rhizopus*, are nonseptate. Septate filamentous fungi can be further divided into nonpigmented hyaline species (e.g., *Fusarium*, *Aspergillus*) and pigmented dematiaceous species (e.g., *Alternaria*, *Curvularia*). Yeasts, such as *Candida* and *Cryptococcus*, are unicellular fungi that reproduce by budding, but in tissue, they might develop elongated buds (pseudo-hyphae) or real hyphae. Dimorphic fungi, such as *Histoplasma*, *Coccidioides*, and *Blastomyces*, demonstrate both a yeast phase that occurs in tissues and a mycelial phase that appears on culture media and saprophytic surfaces.

The incidence of fungal keratitis in the United States has historically been quite low, but rates of *Fusarium* keratitis increased dramatically in the mid-2000s because of an epidemic related to a contact lens solution.<sup>1</sup> Although the rate of *Fusarium* keratitis decreased after the solution was withdrawn from the market, microbiology laboratories have continued to detect elevated numbers of filamentous fungi. Fungal keratitis is more common in tropical climates. In these areas, septate filamentous fungi, most notably *Fusarium* and *Aspergillus*, are the most common causative organisms. In contrast, *Candida* is the predominant cause in more temperate climates.

The risk factors associated with fungal keratitis depend on the setting.<sup>2</sup> In the tropics, corneal trauma, which might be trivial, frequently precedes infection. Concurrent contamination with plant material presents an increased risk for fungal keratitis. However, in colder climates, where *Candida* infections predominate, fungal infections are more commonly seen in patients with corneal pathology or with an ocular surface that is locally immunosuppressed by chronic corticosteroid use or systemic disease.

## CLINICAL FEATURES

Fungal infection tends to arise in traumatized, diseased, and immunocompromised corneas. The keratitis tends to be slowly progressive and insidious, but rapid infiltrate development does not rule out fungal infection. In some cases, the epithelium might heal over an intrastromal infiltrate that produces little inflammation and minimal discomfort. Conversely, inflammation might be so severe as to result in satellite lesions and hypopyon formation. The ulcer and infiltrate itself can assume protean appearances and might be indistinguishable from a bacterial ulcer. However, certain features suggest a filamentous fungal infection, including feathery edges or a dry, gray, elevated infiltrate and satellite lesions (Fig. 4.13.1).<sup>3</sup> Compared with other fungal pathogens, *Aspergillus* may be more likely to have a ring infiltrate, and dematiaceous fungi may be more likely to have a pigmented or raised infiltrate.<sup>4,5</sup> Although a ring infiltrate and endothelial plaque are suggested as indicators of fungal keratitis, many cases do not demonstrate these features, which merely reflect corneal and anterior chamber inflammation.

## DIAGNOSIS

A high level of suspicion for nonbacterial keratitis must be maintained at all times, especially in those areas where the incidence of fungal keratitis is relatively high (Fig. 4.13.2). Important historical elements include pre-existing corneal disease, chronic corticosteroid use, trauma, contact lens wear, and recent surgery, including laser-assisted in situ keratomileusis (LASIK).<sup>6</sup>

Definite diagnosis requires laboratory confirmation. Scrapings for stains and culture should be obtained as described for bacterial keratitis. If fungal infection is suspected after LASIK, the flap must be elevated to obtain samples. Smear diagnosis is primarily made with Giemsa or ink-potassium hydroxide stains, though fungal elements are also visible on Gram stain (Fig. 4.13.3). Gomori's methenamine silver stain is generally considered the stain that best demonstrates fungal organisms.

Culture media used to demonstrate fungal growth include Sabouraud's agar, potato dextrose agar, and brain-heart infusion broth, although many fungi will grow on blood agar kept at room temperature. Most ocular

Fig. 4.13.1 Feathery stromal infiltrates typical of fungal keratitis.

**Fig. 4.13.2** *Fusarium* fungal keratitis.

**Fig. 4.13.3** Gram stain of scraping from corneal ulcer caused by *Fusarium* demonstrating branching fungal hyphae.

fungal isolates demonstrate growth within 2–3 days, although it is prudent to wait 2 weeks before confirmation of no growth. Fungal susceptibility criteria are poorly standardized and not performed at most laboratories.

Corneal scrapings can be investigated with polymerase chain reaction techniques that target a common fungal ribosomal RNA (rRNA), although the high sensitivity of these methods carries the risk of false positives because of contamination, either at the site of corneal scraping or in the laboratory.

In vivo confocal microscopy can be used to detect fungal hyphae and is particularly useful for diagnosis of deep infections that cannot easily be scraped.<sup>7</sup> Fungal filaments appear as highly reflective double-walled structures measuring between 3 and 8  $\mu\text{m}$ .<sup>8</sup>

Since some cases of keratitis may develop deep in the stroma with intact overlying corneal tissue, a deep corneal biopsy might be necessary to obtain tissue for laboratory studies (Fig. 4.13.4).

## DIFFERENTIAL DIAGNOSIS

For the differential diagnosis of fungal keratitis, see Box 4.12.1. As a result of indolent progression and failure to respond to antibacterial medication, fungal keratitis often is misdiagnosed as herpetic or amebic disease. Fungal infection following LASIK must be differentiated from the sterile interface infiltration of post-LASIK diffuse lamellar keratitis and from infection caused by bacterial species.

## SYSTEMIC ASSOCIATIONS

Fungal keratitis caused by less virulent organisms, such as *Candida*, often is associated with conditions that lead to immunocompromise, such as

**Fig. 4.13.4** Keratoplasty specimen demonstrating fungal infiltration of the anterior stroma and inflammatory cells.

**TABLE 4.13.1** Antifungals

Agent	Route	Dosage/Concentration
<b>Polyenes</b>		
Amphotericin B	Topical Subconjunctival Intracameral	0.15% 0.5–1 mg 7.5–10 $\mu\text{g}$ in 0.1 mL
Natamycin	Topical suspension	5%

alcoholism, diabetes, and vitamin A deficiency. Fungal keratitis is not associated with systemic fungemia.

## PATHOLOGY

Destructive fungal infection is advanced by organism adherence, invasion, growth, and subsequent damage caused by direct toxicity and host response. The mycelia of filamentous organisms tend to extend along the corneal lamellae, whereas more virulent organisms can cross lamellae and even penetrate Descemet's membrane, leading to intracameral infection.<sup>9,10</sup> The inflammatory host response is similar to that described in bacterial infection, with both mycotic and host factors leading to an inflammatory cell infiltrate, necrosis, and neovascularization.

## TREATMENT

The efficacy of currently available antifungal agents is limited, and a relatively high medical treatment failure rate exists. The agents most commonly used for fungal keratitis include the polyenes and azoles (Table 4.13.1).

Polyene medications, such as amphotericin B, natamycin, and nystatin, bind to fungal cell wall ergosterol, thus disrupting the cell. The polyenes are effective against both filamentous and yeast forms. Amphotericin B is

particularly effective against yeasts and is the agent of choice for keratitis caused by *Candida* species, but it is less effective against filamentous organisms. Natamycin is effective against yeasts and has a broad spectrum of activity against filamentous organisms. The polyenes do not penetrate well through in an intact corneal epithelium.<sup>11</sup> Periodic debridement of the cornea may enhance penetration of topical medications, although it is unclear that debridement results in better outcomes.<sup>12</sup>

Azole medications, which include the imidazoles (e.g., miconazole, clotrimazole, and ketoconazole) and the triazoles (e.g., fluconazole, itraconazole, posaconazole, and voriconazole) inhibit synthesis of ergosterol in the cell wall. Azoles generally have good activity against yeasts but have more variable activity against filamentous organisms. Voriconazole has good corneal penetration when given topically, and good intraocular concentrations when given orally. Voriconazole can be administered as an intracameral or intrastromal injection.<sup>13</sup> Potential adverse effects of oral voriconazole include visual phenomena and hepatotoxicity; liver function therefore should be monitored.

Other antifungal agents have a role for treatment of fungal keratitis. The pyrimidine flucytosine blocks fungal thymidine synthesis. Flucytosine is well absorbed when administered orally, and it also can be applied as a topical solution. Echinocandins, such as caspofungin and micafungin, inhibit beta-glucan in cell walls and have shown promise as a topical therapy for fungal keratitis.

Once the diagnosis has been made, fungal keratitis should be treated with frequently applied topical antifungal medication. An oral triazole should be considered for deep stromal infection. Ulcers are typically treated with a loading dose (e.g., every 5–15 minutes for the first hour) followed by application every 30–60 minutes. The frequency of applications is reduced on the basis of clinical response. Intracameral injections of amphotericin B or voriconazole can be administered for infections that have penetrated Descemet's membrane.

The Mycotic Ulcer Treatment Trial (MUTT) was a randomized controlled trial that found that fungal ulcers randomized to natamycin had better vision at 3 months compared with those randomized to voriconazole—a result driven largely from the efficacy of natamycin among *Fusarium* ulcers.<sup>14</sup> A companion trial found no benefit to oral antifungal therapy: in MUTT II, fungal ulcers were treated with topical therapy and randomized to oral voriconazole or placebo. After 3 months, the rate of perforation or therapeutic keratoplasty was not significantly different between the voriconazole and placebo groups.<sup>15</sup>

Because these infections can be tenacious, and host suppression of infection is very important, corticosteroid use is generally not recommended in the management of fungal keratitis. However, patients who are already using corticosteroids at the time of diagnosis should have their medication gradually tapered off because abrupt cessation of corticosteroid therapy can result in an intense host inflammatory response leading to perforation.<sup>16</sup> The propensity for corticosteroids to enhance microbial viability can present a particular dilemma for the treatment of fungal infection in a corneal graft. In vitro studies have suggested that topical cyclosporine A might possess antifungal properties, and this agent has been used as an alternative for reducing inflammation and the subsequent risk of graft failure in the setting of fungal graft infection.<sup>17</sup>

The course of treatment is typically protracted. Antifungal treatment is usually maintained over 12 weeks, with strict vigilance as medicines are tapered. If fungal keratitis fails to respond to medical therapy, surgical intervention should be considered. Because of the propensity for fungal elements to invade deeply and, in some cases, penetrate Descemet's membrane, advanced cases require penetrating keratoplasty to ensure complete removal of the invading fungus. In general, penetrating keratoplasty should be performed sooner rather than later to maximize the probability of a graft margin free of infection and to minimize the risk of endophthalmitis or infectious scleritis. As generous a clear margin as possible should be included in the excised cornea.<sup>18</sup> Less advanced cases might be amenable to lamellar keratoplasty, but the surgeon must be confident that the entire infection has been encompassed by the lamellar dissection. If there is any question about the depth of infection, the procedure should be converted to a full-thickness penetrating excision.<sup>19</sup>

## OUTCOME

Patients with deep stromal infection and those treated with corticosteroids appear to respond particularly poorly to medical therapy. Medical failure occurs in approximately 15%–20% of cases.<sup>12</sup> Although penetrating keratoplasty can successfully eliminate the organism and restore the integrity of the eye, a delay in surgery or advanced disease might allow catastrophic extension of infection to the anterior chamber and sclera, especially in the case of preoperative topical corticosteroid use, perforation, or limbal involvement.<sup>20</sup>

# Parasitic Keratitis

Jeremy D. Keenan, Stephen D. McLeod

# 4.14

**Definition:** Corneal disease caused by protozoal organisms.

## Key Feature

- Cellular infiltration of the corneal epithelium or stroma, corneal inflammation, and necrosis.

## Associated Features

- Delay in diagnosis is common.
- Pain may be greater than physical findings.
- Early cases may demonstrate pseudo-dendrites.
- Later cases may show ring infiltrate in the cornea.

## INTRODUCTION

Parasitic infections of the cornea are a significant cause of ocular morbidity. *Acanthamoeba* keratitis is increasingly recognized in the developed world as a potentially disastrous complication of contact lens wear and requires early, aggressive treatment. *Onchocerca* infection is still encountered in some parts of the developing world.

## ACANTHAMOEBA KERATITIS

### Epidemiology and Pathogenesis

*Acanthamoebae*, found ubiquitously in water, soil, and air, are free-living protozoans that exist in an active trophozoite form and a dormant cyst form. The trophozoite feeds on microorganisms and reproduces by binary fission, but if deprived of a food source, it will encyst. Cysts are resistant to desiccation, temperature extremes, and various chemicals and can remain dormant for years. *Acanthamoebae* are typically speciated according to morphological characteristics, although they can also be classified into one of 15 genotypes. The vast majority of keratitis is caused by the T4 genotype.<sup>1</sup>

Keratitis caused by *Acanthamoeba* is less common than that caused by bacteria or fungi, although the incidence of *Acanthamoeba* keratitis increased in the United States for several years in the mid-2000s because of an epidemic related to a contact lens solution.<sup>2</sup> The biggest risk factor for *Acanthamoeba* keratitis in the developed world is contact lens wear, with approximately 90% of cases occurring in contact lens wearers.<sup>3</sup> Most cases are seen in soft contact lens wearers, although orthokeratology may convey increased risk. Trauma is the other major risk factor and accounts for the vast majority of *Acanthamoeba* keratitis seen in developing countries.<sup>4</sup> Other risk factors include exposure to water, especially fresh water sources, swimming pools or hot tubs, and homemade contact lens solutions.

### Clinical Features

Since a delay in treatment has been shown to adversely affect visual outcome, clinicians must be acutely aware of the sometimes subtle early signs of *Acanthamoeba* infection. Early infection is confined to the epithelium, which demonstrates irregularity and multifocal infiltration, pseudo-dendrites, or elevated epithelial ridges (Fig. 4.14.1). Stromal radial perineuritis is thought to be very specific for *Acanthamoeba* keratitis, although it does not appear in many cases (Fig. 4.14.2). Limbitis is common, and may account for significant pain. Later stages of infection are characterized by nonspecific stromal infiltration (Fig. 4.14.3) or a

**Fig. 4.14.1** Epithelial ridges seen in *Acanthamoeba* keratitis. (Courtesy Joel Sugar, MD.)

**Fig. 4.14.2** Perineuritis seen in *Acanthamoeba* keratitis. (Courtesy Joel Sugar, MD.)

**Fig. 4.14.3** Ring infiltrate in corneal *Acanthamoeba* infection.

**Fig. 4.14.4** Double-walled and bright spot cystic structures on confocal microscopy.

characteristic ring infiltrate (Fig. 4.14.4), and uveitis.<sup>5</sup> When present, fluctuating, nongranulomatous anterior chamber inflammation may contribute to the formation of cataract or elevated intraocular pressure. In the most severe cases, hypopyon, anterior scleritis, or perforation (sometimes associated with optic neuritis) can occur.<sup>6</sup>

It has been reported frequently that patients experience severe pain far out of proportion to clinical findings, but this is an unreliable diagnostic sign, and some patients have reduced or absent corneal sensation.

## Diagnosis

Diagnosis is based on characteristic clinical findings and supported by microbiological investigations. Cysts are visible with routine stains, such as Giemsa, Gram, and ink-potassium hydroxide, and with stains that require fluorescent microscopy, such as Calcofluor white and acridine orange.<sup>7</sup> Scrapings should be plated on nonnutrient agar and overlaid with *Escherichia coli* to assess for growth of trophozoites; plates should be observed for longer than 7 days. If plates are not available, scrapings can be transported to the laboratory in Page's saline. Culture and smear of samples from contact lens cases and cleaning solutions also can reveal *Acanthamoeba*.

Polymerase chain reaction (PCR) assays targeting *Acanthamoeba* 18S ribosomal RNA (rRNA) have been shown to be more sensitive than culture or smear but are not currently available at most laboratories.<sup>8</sup>

In vivo confocal microscopy can be used to visualize *Acanthamoeba* cysts in the corneal epithelium and stroma. Cysts appear as round, hyper-reflective structures measuring 10–25  $\mu\text{m}$ , often with a “bright spot” or double-walled morphology (see Fig. 4.14.4).<sup>9</sup> The technique has been shown to have good sensitivity and specificity.<sup>10</sup>

Corneal biopsy should be considered for cases with only deep stromal involvement or when microbiological tests are negative (Fig. 4.14.5). Biopsies should be stained with hematoxylin and eosin, periodic acid–Schiff, and methenamine silver stains.

## Differential Diagnosis

See Box 4.12.1. The pseudo-dendrites of early disease and the ring infiltrate of more advanced disease are often mistakenly identified as representing herpetic keratitis. In those cases that are refractory to treatment, herpetic keratitis and bacterial superinfection should be considered.

## Pathology

Trophozoites bind to the corneal epithelium and establish infection. This is followed by thinning and necrosis of the epithelium, which allow the

**Fig. 4.14.5** Light microscopic view of a corneal section demonstrating *Acanthamoeba* cysts. (Courtesy Joel Sugar, MD.)

organism to enter the stroma, where it may enter progressively deeper layers of the stroma. The organism can become encysted in the corneal stroma and can cause inflammatory sequelae for months after successful antimicrobial treatment.<sup>11</sup>

## Treatment

Treatment of *Acanthamoeba* keratitis is based on eradication of cysts from the cornea.<sup>12</sup> Although trophozoites are susceptible to many antimicrobial agents, the cysts are largely resistant. The most effective medications are the biguanide antiseptic agents chlorhexidine and polyhexamethylene biguanide (PHMB), which act by inhibiting membrane function and are consistently cysticidal (Table 4.14.1).<sup>13</sup> Second-line agents include the diamidines (hexamidine, pentamidine, and propamidine), which inhibit DNA synthesis. Diamidines also generally are cysticidal, though their activity is more variable. Azole medications have activity against trophozoites but are generally not cysticidal. There are reports of effective treatment with oral and topical voriconazole, although the in vitro susceptibility patterns for this agent have not been well characterized. Aminoglycosides such as neomycin and paromomycin were used in the past, but these agents are not cysticidal and cause significant corneal toxicity, so there is little rationale to support their use.

There is little consensus on the best way to treat *Acanthamoeba* keratitis. A clinical trial compared chlorhexidine monotherapy and PHMB monotherapy and found no significant differences, with high success rates in both groups (78% and 86%, respectively).<sup>14</sup> Because cysts can be difficult to eradicate, many clinicians treat with multiple agents, usually with one of the biguanide agents and one of the diamidines. As with other types of infectious keratitis, topical therapy initially should be applied frequently (every 30–60 minutes), and then the frequency can be reduced based on the clinical response. Topical medications generally are continued for many months. Pain should be addressed with cycloplegics and oral nonsteroidal anti-inflammatory drugs.

The role of corticosteroids in the treatment of *Acanthamoeba* infection has not been established. Corticosteroids promote excystment and proliferation of trophozoites and lead to worse visual outcomes when used before starting anti-amebic treatment.<sup>15,16</sup> However, corticosteroids also reduce pain and inflammation and may reduce the likelihood of corneal vascularization. A large retrospective study found that initiation of corticosteroids after a median of 2 weeks of antiamebic therapy was not associated with worse outcomes in eyes with *Acanthamoeba* keratitis and persistent inflammation, providing some reassurance for patients requiring anti-inflammatory therapy.<sup>17</sup> Antiamebic agents should be started before and continued during corticosteroid therapy.

The role of therapeutic keratoplasty for active *Acanthamoeba* keratitis is controversial. Recurrence of *Acanthamoeba* infection has been reported to occur in more than half the grafts, leading to poor postoperative visual outcomes.<sup>18</sup> Others have found much lower rates of recurrence, and good

TABLE 4.14.1 Antiamoebic Medications

Agent	Trade Name	Manufacturer	Dosage Form	Concentration for Ocular Use	Availability	Comment
Cationic Antiseptics						
Chlorhexidine			Solution	0.02%	As 20% concentrate	Used as disinfectant
Polyhexamethylene biguanide (PHMB)	Baquacil	Zeneca	Solution	0.02%	As 20% pool disinfectant	Used also as a preservative, contact lens solutions
Aromatic Diamidines						
Propamidine isethionate	Brolene	Mays & Baker	Solution	0.1% w/v 10 mL	Over-the-counter in UK	
Hexamidine	Désomédine	Chauvin	Solution	0.1%	Available in Europe	
Azoles						
Clotrimazole	Lotrimin	Schering	Suspension	1%	As powder from manufacturer	Poor suspension; difficult to make
Fluconazole	Diflucan	Roerig	Solution	0.2%	As 2 mg/mL solution	Withdraw from vial with filter needle
Ketoconazole	Nizoral	Janssen	Oil solution	5%	As 200 mg tablet	In mortar, dissolve 2.5200 mg tablets in 10 mL of peanut oil
Miconazole	Monistat	Janssen	Solution	1%	As 10 mg/mL solution	Simple 1:1 solution or directly from vial via filter
Voriconazole	Vfend	Pfizer	Oral	200 mg twice daily 1%	As 200 mg tablet As 200 mg vial	Monitor liver function

(Adapted from Richard G. Fiscella, RPh, MPH.)

visual outcomes.<sup>19</sup> Antiacanthamebic medications should be continued after keratoplasty.

Outcome

With timely diagnosis, Acanthamoeba organisms can be eradicated from the cornea by medical therapy. A minority of patients develop rapidly progressive cataract and glaucoma, presumably from prolonged exposure to topical medications or to the host inflammatory response.<sup>20</sup> Severe corneal inflammation and necrosis can result in substantial scarring, necessitating penetrating keratoplasty for visual rehabilitation. Optical keratoplasty performed well after eradication of Acanthamoeba infection carries a good prognosis, but results of therapeutic keratoplasty performed during active infection are much more variable.<sup>18,21</sup>

MICROSPORIDIOSIS

Epidemiology and Pathogenesis

Microsporidia are ubiquitous obligate intracellular parasites closely related to fungi.<sup>22</sup> Although it is a rare disease, diagnosis of microsporidial keratitis is increasing. This is especially true in Asia, where the disease may correspond with the monsoon season.<sup>23</sup> Several risk factors occur for microsporidial keratitis. Immune compromise is the most notable risk factor, especially in persons with human immunodeficiency virus (HIV) infection. Other states of immunosuppression, including local immunosuppression with topical corticosteroids, make infection more likely. Other major risk factors include trauma, which is often associated with exposure to water or mud, and contact lens wear.<sup>24</sup> Although previously considered to occur primarily in the setting of HIV, infection is increasingly being observed in immunocompetent persons.

Clinical Features

Two distinct clinical presentations are possible with ocular microsporidial infection: superficial keratoconjunctivitis, which is caused by encephalitozoon species, and deep stromal keratitis, which is caused by nosema, vittaforma, and trachiplestophora species. The keratoconjunctivitis form usually was seen in immunocompromised persons in the past, although this entity is now recognized in immunocompetent persons as well.<sup>25</sup> Microsporidial keratoconjunctivitis is characterized by minimal conjunctivitis, diffuse punctate epitheliopathy, and coarse epithelial opacities, some of which stain with fluorescein. Symptoms include pain, photophobia, blurred vision, and foreign body sensation. Microsporidial stromal keratitis usually is seen in immunocompetent individuals, where it is often misdiagnosed as herpetic keratitis. Stromal infection is characterized by deep stromal infiltrates with or without corneal neovascularization and uveitis.

Diagnosis

Diagnosis of microsporidial keratitis usually is made by inspection of smears obtained from corneal or conjunctival scrapings. Several stains

can be used, with potassium hydroxide plus Calcofluor white, Gram, and modified Ziehl–Neelsen most consistently detecting microsporidia.<sup>26</sup> Giemsa staining characteristics are more variable. Microsporidia are difficult to recover in culture. PCR assays that target the 16S rRNA subunit have been developed but are not performed by most laboratories.<sup>27</sup> The confocal microscope can reveal intraepithelial microsporidia, but these organisms, which measure 1–5 μm, approach the resolution limits of this instrument.<sup>28</sup> Electron microscopy performed on body fluids is considered the gold standard for diagnosis of microsporidial infection.

Differential Diagnosis

See Box 4.12.1.

Systemic Associations

Microsporidial infection can involve nearly every organ system in severely immunocompromised patients with HIV infection (usually CD4 cell counts <100/μL). The gastrointestinal system is most commonly involved, representing a major cause of malabsorption and diarrhea in patients with acquired immunodeficiency syndrome (AIDS). Ocular infections are second in frequency and may result from nasopharyngeal infection or from urine-to-finger-to-eye contamination. When ocular microsporidial infections are diagnosed, the patient must be fully examined for other areas of involvement. Other common infections include sinusitis, hepatitis, peritonitis, cholangitis, myositis, bronchiolitis, pneumonia, encephalitis, cystitis, and nephritis. Rare manifestations include urethritis, prostatic abscess, tongue ulcer, and skeletal and cutaneous involvement.

Treatment

The optimal treatment regimen for ocular microsporidiosis is not well defined. Several medications are currently used, including oral agents, such as albendazole and itraconazole, and topical agents, such as fumagillin, propamidine, chlorhexidine, PHMB, voriconazole, and the fluoroquinolones. Fumagillin is one of the more frequently used medications; a 10 mg/mL suspension can be applied hourly for 24 hours and then tapered based on clinical response. Albendazole has been used when ocular microsporidiosis was refractory to topical therapy.<sup>29</sup> A placebo-controlled randomized clinical trial performed with immunocompetent patients found no benefit of PHMB.<sup>30</sup> This trial found that the disease may be self-limiting in immunocompetent patients; the placebo group experienced clinical cure an average of 9 days after diagnosis.

Outcome

Treatment of microsporidial keratoconjunctivitis is usually successful, especially in immunocompetent patients. Immunocompromised persons can develop chronic infections when antimicrosporidial treatment is withdrawn. In such an event, a low maintenance dose of one drop a day might be sufficient to control the keratoconjunctivitis. Visual acuity improvement is usually seen after the superficial keratitis resolves.<sup>30</sup> Disease involving

the corneal stroma is difficult to treat, and recrudescence is common. Some authors advocate full-thickness keratoplasty in these cases because microsporidia can invade the anterior chamber, and lamellar keratoplasty does not preclude recurrence.<sup>31</sup>

## ONCHOCERCIASIS

### Epidemiology and Pathogenesis

Onchocerciasis, also known as “river blindness,” is a major cause of blindness worldwide. Onchocerciasis affects approximately 18 million people, of whom 270 000 are rendered blind.<sup>32</sup> The vast majority of cases occur in the 34 countries in Africa where the disease is still endemic. The causative organism, *Onchocerca volvulus*, is a filarial nematode that is transmitted by the Simulium black fly, which breeds in the fast-flowing rivers and streams of Africa, Brazil, Mexico, the Middle East, and parts of Central America. The fly introduces larvae of *O. volvulus* into the skin during a blood meal, forming a skin nodule of adult worms. After developing into adult worms, females shed hundreds of thousands of microfilariae that migrate through skin and have particular affinity for eyes. Dying microfilariae incite an inflammatory reaction that results in the cutaneous and ocular clinical manifestations. An endosymbiont bacteria, *Wolbachia*, plays an important role in development of larvae, and also possibly in the long-term survival of adult worms.<sup>33</sup>

Eye disease is related to the inflammatory response generated by the nematodes, which can be found in the conjunctival epithelium, corneal stroma, iris, ciliary body, sclera, extraocular muscles, and optic nerve sheath. The severity of ocular findings depends on the strain of microfilariae; strains from the savanna regions of West Africa induce a more severe inflammatory response and sclerosing keratitis, which is typically absent in infections caused by the rain forest strain.<sup>34,35</sup>

### Clinical Features

Early infection with the *Onchocerca* worm is marked by a diffuse papular dermatitis, accompanied by intense pruritus.<sup>32</sup> Other cutaneous findings can range from lichenification to asymptomatic depigmentation to subdermal nodules. Onchocerciasis can involve virtually all ocular tissues. Lid nodules and edema, chronic conjunctivitis with injection, chemosis, and phlyctenule-like conjunctival masses can develop. Corneal involvement is marked by a fine interpalpebral epithelial punctate keratitis that overlies white subepithelial flake-like opacities and discrete nummular scars, and stromal edema caused by an intrastromal worm. These worms can be visualized at the slit lamp on retroillumination at all corneal levels as S- or C-shaped fine, motile filaments. Sclerosing keratitis represents more severe, blinding corneal disease. It tends to appear as an anterior stromal haze centered at the 3 and 9 o'clock positions separated from the limbus by a clear zone. Both infiltration and neovascularization are progressive and can encroach on the visual axis as the entire cornea becomes involved. Calcific band keratopathy and uveitis can develop, as well as scleritis.

Microfilariae might be observed in the anterior chamber, especially in the inferior angle on gonioscopy, or on the anterior lens capsule. In some cases, the accompanying uveitis can be severe, leading to corectopia, synechiae, occluded pupil, and secondary glaucoma. Chorioretinal lesions appear as asymmetrical lesions peripheral to the macula or around the optic nerve. Peripapillary chorioretinitis with optic nerve edema can result in optic atrophy, another significant cause of visual impairment.

### Diagnosis

Diagnosis is based on observation and identification of the worm. It can be recovered from skin from an excised nodule or from a bloodless skin snip from the scapula, iliac crest, or lower calf. The worm count in skin snips is correlated with the intensity of infection. Serological tests are available, although some have difficulty discriminating *O. volvulus* from other filarial infections.<sup>36</sup>

### Differential Diagnosis

Similar skin lesions can be seen in association with microfilarial infection caused by *Mansonella perstans*. Skin nodules and uveitis also can be seen with sarcoidosis.

### Systemic Associations

Besides being present in skin lesions, the microfilariae can be identified in blood vessels, visceral organs, the central nervous system, urine, and sputum. Superficial lymph nodes draining areas with cutaneous concentrations of the worms can become painlessly enlarged.

### Pathology

The destructive inflammation caused by *Onchocerca* infection is stimulated by antigens released by dead and dying organisms. The host immune response results in migration of eosinophils and neutrophils into the corneal stroma. Degranulation of these inflammatory cells releases cytotoxic proteins that disrupt the normal functioning of the corneal cells, resulting in corneal opacity.<sup>37</sup>

### Treatment

The skin nodule containing the adult worms should be surgically removed. Oral ivermectin kills microfilariae but not adult worms. A 6-week course of doxycycline 100–200 mg/day is used to clear *Wolbachia* endosymbionts and results in long-term sterilization of adult worms.<sup>38</sup> Ivermectin has been shown to reverse even advanced sclerosing keratitis and iridocyclitis, but treatment is not effective for chorioretinal lesions, which progress despite treatment.<sup>39</sup> Iridocyclitis should be treated with corticosteroids and cycloplegia. From a public health perspective, the mainstay of treatment is oral ivermectin given as a single dose (150 µg/kg) repeated annually or biannually. Mass drug administrations are delivered to entire communities in endemic areas.

### Outcome

Although anterior segment inflammation and lesions respond well to treatment, severe visual impairment can result from chorioretinitis, which, in advanced cases, often continues to progress in spite of treatment. Health programs are aimed at blindness prevention through mass treatment, prevention, and vector control. Evidence exists that prolonged repeated mass ivermectin distributions can disrupt transmission of *O. volvulus*, suggesting that elimination of disease may eventually be possible.<sup>40</sup>

# Herpes Simplex Keratitis

Sonal S. Tuli, Matthew J. Gray

4.15

**Definition:** Herpes simplex viral infection of the cornea.

**Key Features**

- Dendritic ulcer: classic feature of epithelial disease.
- Focal endotheliitis (disciform keratitis): classic feature of stromal disease.

**Associated Features**

- Decreased corneal sensation.
- Underlying granulomatous keratic precipitates.

**EPIDEMIOLOGY**

Human herpesviruses (Table 4.15.1) have in common a state called “latency,” where the virus remains dormant in cells and periodically reactivates. Herpes simplex viruses 1 and 2 (HSV-1 and HSV-2) have an affinity for the sensory ganglion cells and, therefore, are called *neurotrophic viruses*. These viruses are ubiquitous, and in most parts of the world, exposure to HSV-1 is almost universal by late adulthood.<sup>1,2</sup> HSV keratitis (HSVK) is the most common cause of corneal blindness in developed nations.<sup>3</sup> In the United States, the incidence of new cases of HSVK is estimated at 24000 per year, and the total number of episodes at 58000 per year with a prevalence over 400000.<sup>4,5</sup> HSV-1 infections more commonly occur in the orolabial area and HSV-2 in the genital area.<sup>6</sup>

**HERPES SIMPLEX VIRUS**

HSV, a large double-stranded DNA virus, has an icosahedral capsid surrounded by a poorly defined tegument enclosed in a host cell membrane-derived envelope with viral-derived glycoprotein projections (Fig. 4.15.1).

Newly formed virions, which replicate in the cell nucleus, egress by budding from the cell membrane, destroying the cell in the process. Recurrent infections progressively destroy sensory ganglion cells, diminishing corneal sensation, one of the hallmarks of HSVK.

Serum antibody production to HSV infections is inconsistent and only partially protective. The major immune response to HSV is T lymphocyte mediated.<sup>7,8</sup>

**Life Cycle of HSV**

Initial HSV infection is usually asymptomatic and occurs by direct contact of mucous membranes with infected secretions rather than by fomites

or aerosolization. The virus enters epithelial cells on contact, replicates, enters the sensory nerve endings, and travels in a retrograde fashion to the trigeminal ganglion, where it remains *latent* (Fig. 4.15.2). The cornea also may be a site of HSV latency and replication.<sup>9–13</sup> After an initial round of replication in the trigeminal ganglion, the virus travels back down the nerve in an antegrade fashion, causing *primary* infection in about 6% of patients. It then remains latent until certain triggers cause it to reactivate, replicate, and travel back down the nerve to cause *recurrent* infection. It is not clear if the initial infection occurs by direct contact of ocular tissues with infected secretions, or if the initial infection occurs in the orolabial area with the virus then spreading to the neurons supplying the eye in the trigeminal ganglion (back-door spread).<sup>12</sup>

**PRIMARY HSV INFECTION**

Primary HSV ocular infection most commonly manifests as blepharoconjunctivitis (often with conjunctival ulceration) that heals without scarring (Fig. 4.15.3). The associated follicular conjunctivitis is often mistaken for adenoviral conjunctivitis (Fig. 4.15.4); up to a third of unilateral follicular conjunctivitis may be culture-positive for HSV.<sup>14–16</sup> Other features include lid vesicles and conjunctival dendrites. Keratitis is rare, occurring in only 3%–5% of cases, although severe bilateral disease can occur in atopic or immunocompromised patients.<sup>5,17–19</sup>

**RECURRENT HSV INFECTIONS**

Multiple factors are thought to trigger recurrence, including fever, menses, sunlight, irradiation, and emotional stress. Anecdotal reports have also implicated prostaglandin analogues, immunosuppression, and refractive surgery. Recurrent disease, estimated to occur in 27% of patients at 1 year and over 60% at 20 years, commonly causes keratitis (HSVK), although it can affect all parts of the eye.<sup>5</sup> The risk of a subsequent recurrent infection increases with the number of recurrences to 83% at 20 years after one or more recurrences.<sup>5</sup>

HSVK is broadly classified into epithelial and stromal/endothelial keratitis. This classification not only is anatomical but also is important for understanding the pathophysiology of HSVK and for planning treatment.

TABLE 4.15.1 Human Herpesviruses of Medical Importance		
Abbreviation	Nomenclature	Disease Caused
HSV-1	Herpes simplex type-1	Oral, ocular, genital herpes, whitlow
HSV-2	Herpes simplex type-2	Genital, oral, ocular herpes, whitlow
VZV	Varicella zoster virus	Chickenpox, herpes zoster (shingles)
CMV	Cytomegalovirus	Retinitis, range of systemic diseases
EBV	Epstein–Barr virus	Infectious mononucleosis
HHV-6	Human herpesvirus-6	Exanthem subitum (roseola)
HHV-7	Human herpesvirus-7	Exanthem subitum (roseola)
KSRV	Kaposi’s sarcoma–related virus	Kaposi’s sarcoma

Fig. 4.15.1 Herpes simplex virus (HSV) structure.

Fig. 4.15.2 Life cycle of herpes simplex virus (HSV).

Fig. 4.15.3 Blepharoconjunctivitis.

### Epithelial Keratitis

Caused by actively replicating virus on the corneal surface, this usually starts as epithelial vesicles, punctate keratitis, or opaque plaques that coalesce and break down centrally. Initial episodes present with foreign body sensation, but subsequent episodes usually are painless because of

Fig. 4.15.4 Follicular conjunctivitis.

corneal hypoesthesia.<sup>20</sup> However, the associated inflammation may cause significant photophobia. It includes the conditions discussed below.

### Dendritic Ulcer

This classic herpetic lesion consists of a linear, dichotomously branching lesion with terminal bulbs (Fig. 4.15.5). The borders consist of acantholytic, infected cells and are slightly raised, grayish, and stain with Rose Bengal

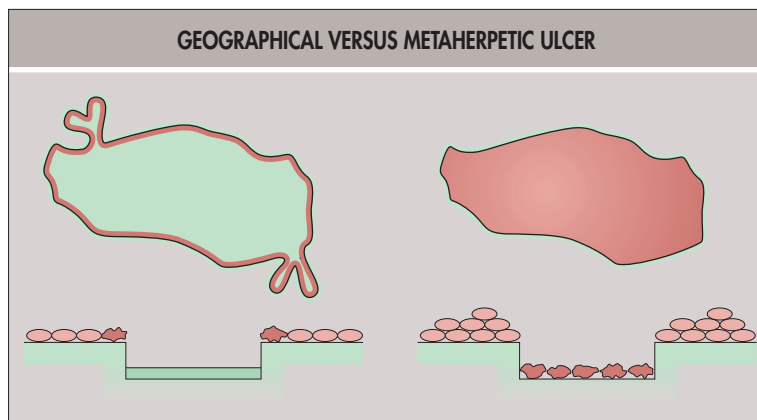

**Fig. 4.15.5** Dendrite.

**Fig. 4.15.7** Disciform keratitis.

**Fig. 4.15.6 Geographical Versus Metaherpetic Ulcer.** Geographical ulcer (*left*): large fluorescein-staining epithelial defect with peripheral dichotomous branching and terminal bulbs that stain with Rose Bengal metaherpetic ulcer (*right*): Rose Bengal staining of unhealthy epithelial cells across ulcer base and fluorescein leakage into stroma and periphery (reverse staining). Note heaped up epithelial cells at ulcer edge.

stain. The central epithelial defect stains with fluorescein. The underlying stroma may have minimal inflammation. On resolution, a dendrite-shaped scar, called *ghost dendrite*, may remain in the superficial stroma.

### Geographical Ulcer

Patients who are immunocompromised, on topical corticosteroids, or have long-standing, untreated ulcers can develop very large epithelial defects.<sup>21</sup> However, dichotomous branching and terminal bulbs are often seen at the periphery and the staining is similar to dendritic keratitis.

### Marginal Keratitis

These lesions located near the limbus can resemble staphylococcal catarrhal ulcers. An epithelial defect and lack of corneal sensation can aid in diagnosis. Significant stromal inflammation can occur because of the proximity to limbal blood vessels. More resistant to treatment, they frequently become trophic ulcers.<sup>22</sup>

### Metaherpetic (Trophic) Ulcer

This is not associated with live virus and results from inability of the epithelium to heal (Fig. 4.15.6). It is called a *trophic ulcer* if it arises de novo or a *metaherpetic ulcer* if it follows a dendrite or geographical ulcer, although the terms are used interchangeably. The causes are multifactorial and include toxicity from antiviral medications, unrecognized trauma, lack of neural-derived growth factors, poor tear surfacing, and underlying, low-grade stromal inflammation. Neurotrophic ulcers start as roughened epithelium that breaks down to produce an epithelial defect with smooth margins. The borders are grayish, elevated, and consist of multiple layers of epithelium. In contrast to geographical ulcers, Rose Bengal stains the unhealthy epithelial cells attempting to migrate across the base of the ulcer

while fluorescein leaks between these poorly adherent cells into the stroma and stains the periphery—so-called “reverse staining” (see Fig. 4.15.6).

## Stromal/Endothelial Keratitis

Usually an immune-mediated response to nonreplicating viral particles, stromal keratitis can affect all layers of the cornea and may even involve the trabecular meshwork and iris. It is classified based on the predominant site and type of involvement.

### Endotheliitis

This is the most common form, and it manifests as overlying stromal edema from endothelial dysfunction. Long-standing stromal edema leads to permanent scarring and decreased vision.

### Localized Endotheliitis

This appears as a disc-shaped area of corneal edema called *disciform keratitis* (Fig. 4.15.7). Minimal stromal inflammation occurs without epithelial involvement, although microcystic edema and bullae may develop later in some cases. Focal keratic precipitates underlying the edema are highly suggestive but may be difficult to visualize. Sharp demarcation between involved and uninvolved stroma distinguishes this from other causes of stromal edema.

### Diffuse and Linear Endotheliitis

These are rare and usually accompanied by trabeculitis and elevated intraocular pressure. Pseudo-guttae and Descemet's folds may cause confusion with Fuchs' dystrophy. Linear keratic precipitates can resemble allograft rejection.

### Necrotizing Keratitis

The significantly greater inflammation is thought to be a reaction to live viral particles in the corneal stroma (Fig. 4.15.8). It is most commonly seen in patients with multiple recurrences, especially with HSV-2. Difficult to distinguish from other causes of microbial keratitis without a high index of suspicion, it may cause corneal melting and perforation. Frequently, it is associated with uveitis and trabeculitis that may lead to recalcitrant glaucoma.

### Immune Stromal Keratitis

This manifests as focal, multifocal, or diffuse stromal opacities or an immune ring (Fig. 4.15.9). It often is accompanied by stromal edema and a mild anterior chamber reaction. The epithelium and endothelium are relatively spared. It also is called interstitial keratitis (IK) and can lead to deep stromal vascularization. HSV is now the most common cause of IK, especially unilateral, in the United States.<sup>13</sup> Unlike syphilitic IK, HSV neovascularization is usually unilateral, sectoral, at multiple levels within the stroma, and leads up to a stromal scar.

### Lipid Keratopathy

Newly formed or inflamed vessels are permeable to lipid because of the action of vascular endothelial growth factor. Once exuded, the lipid collects

**Fig. 4.15.8** Necrotizing keratitis.

**Fig. 4.15.9** Interstitial keratitis with lipid keratopathy.

within keratocytes and intercellular matrix and is the major cause of vision loss requiring corneal transplantation in patients with HSV.

### Keratouveitis

Uveitis is usually granulomatous with large “mutton fat” keratic precipitates on the endothelium (Fig. 4.15.10). Although often immune mediated, sectoral iritis with a plasmoid aqueous is caused by release of live virus from the sympathetic nerves.<sup>23</sup> It can lead to significant morbidity from synechiae, iris atrophy, cataracts, and glaucoma. Unilateral uveitis with high intraocular pressure often is caused by HSV.

### Miscellaneous Syndromes

Herpes has been implicated in various chronic, unilateral diseases of the iris and trabecular meshwork. HSV DNA has been isolated by polymerase chain reaction (PCR) from the endothelium of corneas with iridocorneal endothelial (ICE) syndrome and from the aqueous humor of patients with Posner–Schlossman syndrome and Fuchs’ heterochromic iridocyclitis.<sup>24–26</sup>

## DIAGNOSIS

Diagnostic testing is seldom needed in epithelial HSVK because of its classic clinical features and is not useful in stromal keratitis as live virus rarely is present.

**Fig. 4.15.10** Keratouveitis.

## Culture

Corneal swabs placed in viral or chlamydia transport media are transported at 4°C. Cultures following Rose Bengal corneal staining may be falsely negative as Rose Bengal is virucidal with exposure to light.<sup>27</sup> Unfortunately, intracellular HSV is unaffected, and Rose Bengal cannot be used in vivo.<sup>28</sup>

## DNA Testing

PCR is very rapid and extremely sensitive and specific. Strains also can be identified for epidemiological purposes. This is rapidly becoming the testing of choice for viral diseases.

## Fluorescent Antibody Testing

A nitrocellulose membrane or corneal swab smeared on a slide may be used. This gives rapid results, but sensitivity and specificity are lower than those of culture. Fluorescein staining interferes with this test.<sup>29</sup>

## Tzanck’s Smear

Papanicolaou or Giemsa stains of corneal smears show multinucleated giant cells and intranuclear eosinophilic inclusion bodies (Cowdry type A). Although low in sensitivity and specificity, this rapid and cheap test can be done in most laboratories.

## Serum Antibody Testing

Immunoglobulin M (IgM) or rising titers of IgG may be present in children but most adults have IgG to HSV, limiting its use in diagnosis.<sup>1</sup>

## HERPETIC EYE DISEASE STUDY

Prior to the Herpetic Eye Disease Study (HEDS), the standard therapy for all forms of HSVK was with topical antivirals. The HEDS was undertaken to assess the effect of adding corticosteroids and acyclovir to conventional therapy with trifluridine (TFT). It was a prospective, randomized, double-masked, placebo-controlled, multicenter study divided into six trials: three therapeutic, two preventive, and one cohort.

1. **Herpes Stromal Keratitis, Not on Corticosteroid Trial:** Compared with the placebo group, patients receiving prednisolone phosphate drops had faster resolution and fewer treatment failures. However, delaying corticosteroid treatment did not affect the eventual visual outcome.<sup>30</sup>
2. **Herpes Stromal Keratitis, on Corticosteroid Treatment:** There was no apparent benefit in adding oral acyclovir to topical corticosteroids and TFT. However, visual acuity improved over 6 months in more patients on acyclovir.<sup>31</sup>
3. **Herpes Simplex Virus Iridocyclitis, Receiving Topical Corticosteroids:** More treatment failures occurred in the placebo group than in the acyclovir group, indicating a potential benefit to adding oral acyclovir to topical corticosteroids and antivirals.<sup>32</sup>

A meta-analysis of these three trials evaluated the risk of subsequent epithelial keratitis in patients with stromal keratouveitis. Although the risk was higher in the corticosteroid-alone group, it was not statistically

TABLE 4.15.2 Current Antivirals

Drug (Trade Name)	Route	Dose	Frequency	Adverse Effects
Trifluridine (Viroptic)	Topical drops	1.00%	Every 2 hours	Follicular conjunctivitis, epitheliopathy
Vidarabine (Ara-A)(compounded)	Topical ointment	3.00%	Five times a day	As above
Ganciclovir (Zirgan)	Topical gel	0.15%	Five times a day	Stinging, burning, blurring of vision
Acyclovir (Zovirax)	Topical ointment Oral – treatment Oral –prophylaxis	3.00% 400 mg 400 mg	Five times a day Five times a day Twice a day	Headache, nausea, nephrotoxicity, neurotoxicity
Valacyclovir (Valtrex)	Oral –treatment Oral –prophylaxis	500 mg 500 mg	Three times a day Once a day	As above, thrombotic thrombocytopenic purpura and hemolytic uremic syndrome in immunosuppressed
Famciclovir (Famvir)	Oral –treatment Oral –prophylaxis	250 mg 250 mg	Three times a day Once a day	As acyclovir

significant. The risk was also higher in patients with a previous history of epithelial keratitis and in nonwhite patients.<sup>33</sup>

4. **Herpes Simplex Virus Epithelial Keratitis Trial:** In the treatment of acute HSV epithelial keratitis with TFT, the addition of oral acyclovir offered no additional benefit in preventing subsequent stromal keratitis or iritis.<sup>34</sup>
5. **Acyclovir Prevention Trial:** Oral acyclovir reduced the risk of any form of recurrent ocular herpes by 41% and stromal keratitis by 50%. The risk of multiple recurrences decreased from 9% to 4%. However, the protection did not persist once acyclovir was discontinued.<sup>35</sup>
6. **Ocular HSV Recurrence Factor Study:** No association was found between psychological or other forms of stress and HSV recurrences.<sup>36</sup> Previous episodes of epithelial keratitis were not a predictor for future occurrences, whereas previous, especially multiple, episodes of stromal keratitis markedly increased the probability of subsequent stromal keratitis.<sup>37</sup>

This study had some limitations:

1. Many of the trials had inadequate recruitment or high dropout rate.
2. Oral acyclovir in the prevention trials was only used for 3 weeks.
3. The corticosteroid regimen was standardized and not tailored to inflammation.
4. TFT was used in both the study and placebo groups in all the therapeutic trials.

## TREATMENT

Treatment of HSV is diametrically different for epithelial and stromal keratitis, reflecting the fact that epithelial disease is caused by live replicating virus, whereas stromal disease is essentially an immune response to viral antigen. Prompt and appropriate treatment may minimize the risk of scarring, the major cause of morbidity from HSVK.

### Infectious Epithelial Keratitis

Although epithelial keratitis spontaneously resolves in approximately 50% of cases, treatment is advised for ulcers larger than 4 mm, marginal ulcers, and ulcers with underlying stromal inflammation. Topical antivirals, the mainstay of treatment, are very effective and have a low incidence of resistance. Both topical trifluridine and ganciclovir have proven to be successful in the treatment of epithelial keratitis and are commercially available in the United States.<sup>38,39</sup> Gentle wiping debridement is a very good adjunct therapy as infected cells are poorly adherent. This results in much faster resolution, less inflammation, and consequently less scarring.<sup>40</sup> Off-label use of oral antivirals also appears to be a safe and effective alternative to topical therapy.

### Stromal Keratouveitis

The mainstay of treatment is topical corticosteroids because they decrease inflammation and, thus, scarring. Simultaneous antiviral prophylaxis is recommended because evidence suggests that HSV reactivation while on corticosteroids results in severe epithelial disease or necrotizing keratitis. Oral antivirals are preferred because they decrease the risk of HSV reactivation at the ganglion level and do not have the corneal toxicity associated with topical antivirals. Aggressive topical and systemic antivirals along with corticosteroids are necessary in necrotizing keratitis and focal serous iritis.

### Metaherpetic Keratitis

The basic principle is surface support including elimination of toxic medications, punctal occlusion, artificial tear supplements, bandage contact lenses, autologous serum tears, and amniotic membrane grafts.<sup>41</sup> The cautious use of topical corticosteroids may be necessary if there is significant underlying inflammation.

## Medications

### Antivirals

All current antivirals are nucleoside analogs that competitively inhibit viral DNA polymerase (Table 4.15.2). They also may interfere with host DNA synthesis and cause significant toxicity. Acyclovir and ganciclovir are the most specific for viral polymerase and thymidine kinase and, therefore, are the least toxic. Acyclovir resistant HSV-1 has been reported and requires monitoring for cases of HSVK refractory to this treatment.<sup>42–44</sup>

### Corticosteroids

Typically, either 1% prednisolone acetate or 0.1% dexamethasone are used. The frequency should be based on the severity of inflammation and tapering must be very gradual to prevent rebound inflammation.

## Surgery

Surgery is usually performed when corneal scarring limits vision. However, surgery also may be necessary as a therapeutic measure in patients with nonhealing ulcers or impending perforations from necrotizing keratitis.

### Penetrating Keratoplasty

When penetrating keratoplasty is considered, it is preferable to wait at least 6 months after an episode of HSVK before attempting corneal transplantation because the success rate increases in a quiescent eye.<sup>45</sup> Unfortunately, the results of corneal transplantation for HSVK are uniformly poor. Reactivation and rejection occur in 44% and 46%, respectively, by 2 years.<sup>45</sup> Prophylactic acyclovir started prior to surgery and continued for at least 6 months to 2 years decreases the risk of HSVK recurrence and graft failure.<sup>46,47</sup> Lifelong oral prophylactic antivirals may be considered because the HEDS found that the risk of recurrence increases to baseline on stopping antiviral prophylaxis. Lamellar grafts are not recommended because recurrence occurs at the interface.

### Conjunctival Flap

This may be useful in patients with medical contraindications for surgery or chronically inflamed keratitis. Ambulatory vision may be possible through the flap.

### Amniotic Membrane Transplantation

Amniotic membrane transplantation aids the healing of neurotrophic ulcers in HSVK, presumably by decreasing inflammatory cell and matrix metalloproteinase levels in the cornea.<sup>48</sup>

## FUTURE DIRECTIONS

Heat shock and glycoprotein subunit vaccines have shown some promise in clinical trials in decreasing the number and severity of recurrences.<sup>49</sup> Immunomodulatory factors, such as cytokines may serve as adjuncts to corticosteroid therapy by skewing the immune response toward milder disease.<sup>50</sup> Newer antivirals such as cidofovir may be more effective and

cause less toxicity compared with current therapy.<sup>51,52</sup> Interferon, although ineffective as monotherapy, increases the efficacy of antivirals, and other agents, such as nerve growth factor and apolipoprotein E mimetic peptide, have shown a benefit in animal models of HSVK.<sup>40,51–54</sup> Gene therapy may prove to be useful in the future—ribozymes and small interfering RNAs have shown promise in cell culture experiments, but their instability in vivo has been a barrier to clinical use.<sup>55</sup>

## Peripheral Ulcerative Keratitis

Sarkis H. Soukiasian

4.16

**Definition:** Destructive inflammation of the peripheral cornea associated with corneal epithelial sloughing and keratolysis.

**Key Features**

- Peripheral corneal ulceration.
- Unilateral or bilateral.
- Progresses circumferentially and posteriorly and may perforate.
- May be associated with systemic collagen vascular diseases.
- Can be a presenting feature of a previously undiagnosed systemic collagen vascular disorder.
- Frequently requires systemic immunosuppressive immunomodulatory therapy.
- Imperative to exclude a primary or secondary infectious etiology.

**Associated Features**

- Episcleritis.
- Scleritis.
- Iridocyclitis.

**INTRODUCTION**

Peripheral ulcerative keratitis (PUK) is used to describe a group of destructive inflammatory diseases involving the peripheral cornea whose final common pathway is characterized by sloughing of corneal epithelium and keratolysis (corneal “melting”). The vast majority of cases are mediated by local and systemic immunological processes, although some cases may be infectious in origin and must be properly evaluated. PUK may be associated with systemic vasculitides, particularly the collagen vascular diseases, in about half of the noninfectious cases.<sup>1</sup> Necrotizing scleritis often is associated in such cases<sup>1</sup> and is suggestive of possible active vasculitis, with PUK being the presenting feature of a systemic inflammatory condition, such as granulomatosis with polyangiitis (GPA) (formerly known as Wegener’s granulomatosis) or polyarteritis nodosa. If not properly treated, PUK can progress to perforation resulting in significant ocular morbidity, and when associated with a systemic autoimmune condition, may be potentially life-threatening.<sup>2</sup>

**ANATOMY AND PATHOGENESIS**

The unique characteristics and anatomy of the peripheral cornea contributes to the predilection of this region to be involved in both local and systemic immunological reactions.<sup>3,4</sup> There are no clear-cut borders that delineate the peripheral cornea, with an arbitrary central limit beginning around 3.5–4.5 mm from the visual axis and extending out to the junction of the ill-defined transition between limbus and the sclera and conjunctiva. Distinct anatomical differences of the peripheral cornea include the greater thickness (up to 0.7 mm) with tight collagen bundle packing; a vascular arcade that originates from the anterior ciliary arteries and extends approximately 0.5 mm into the clear cornea (providing the nutritional supply but also access to the efferent arm of the immune response); and accompanying lymphatics, which drain to the regional lymph nodes.<sup>5</sup> There also are unique immunological characteristics of the peripheral cornea compared with the central cornea, including the presence of more Langerhans’ cells,<sup>6,7</sup> and higher concentrations of immunoglobulin M<sup>8</sup> and the first component of complement (C1) (important in the activation of the classic complement pathway), likely caused by limited central diffusion from the

limbal vessels resulting from the large size of the latter two molecules. Additionally, the adjacent conjunctival blood vessels and lymphatics not only provide peripheral corneal access to the afferent and efferent arcs of the immune system but may be sources of inflammatory effector cells and cytokines involved in the production of collagenase and proteoglycanase, which may contribute to corneal degradation.<sup>9,10</sup>

Although the exact pathophysiological mechanisms of PUK are unclear, circulating immune complex deposition, autoimmune reactions to corneal antigens, and hypersensitivity reactions to exogenous antigens have been proposed, with evidence suggesting that both humoral and cell-mediated mechanisms (T cell and B cell) are involved.<sup>11–13</sup> Locally produced or circulating immune complexes lodged in limbal or peripheral corneal blood vessels may activate the classic complement pathway in the presence of C1 (the recognition unit of the classic complement pathway). Immune vasculitis resulting in damage to the vessel wall with leakage and the chemotaxis of various inflammatory cells, proteins, and proinflammatory cytokines and the production of metalloproteinases by local resident cells may accelerate and propagate the peripheral corneal destructive process.

**OCULAR MANIFESTATIONS**

The presenting symptoms of PUK are not specific. Foreign body sensation, pain, and photophobia are seen when there is epithelial erosion and ulceration. Vision may be affected if the peripheral inflammatory process proceeds centrally or from induced astigmatism. Occasionally, an associated anterior uveitis may contribute to the photophobia with reduction of visual acuity. Pain may be severe if associated scleritis occurs.

The hallmark clinical features include epithelial loss, demonstrated with fluorescein staining, and various amounts of stromal inflammatory infiltration, and/or thinning caused by keratolysis (corneal melting), which may occur at any clock hour of the peripheral cornea, with or without an intervening clear zone from the limbus (Fig. 4.16.1). The process may progress circumferentially, centrally, and posteriorly, potentially resulting in perforation (Fig. 4.16.2). The specific clinical findings at presentation will depend on the severity and rate of progression of the disease, as well as the timing between the onset and clinical evaluation. Corneal melting, once initiated, may progress very rapidly. The amount of stromal loss may be underappreciated because of debris and necrotic material deposited at the

**Fig. 4.16.1 Patient With Early Nasal Peripheral Ulceration Measuring About 1 O’ Clock Hour.** There is inflammatory stromal infiltrate more central to the ulceration with associated episcleral inflammation.

**Fig. 4.16.2 Progressive Circumferential Peripheral Corneal Ulceration.** (A) A 60-year-old female with idiopathic peripheral ulcerative keratitis. Slit-lamp microscopy demonstrates depth of stromal necrosis. There is inflammatory infiltrate at both the peripheral and central edges. (B) Fluorescein staining demonstrates area of ulceration.

base of the ulcer but may become more apparent after corneal scrapings are performed to evaluate for infectious causes. Limbal, conjunctival, and episcleral injections occur frequently. Concurrent scleritis denotes a higher likelihood of active vasculitis.<sup>1</sup> The finding of PUK with scleritis portends a worse ocular and systemic outcome than when scleritis occurs alone.<sup>14</sup> Cataract and glaucoma may occur as a result of the inflammatory process or the use of corticosteroids.

## SYSTEMIC ASSOCIATIONS

Nearly 50% of patients with PUK have an associated systemic disease, with the large majority of these being the collagen vascular diseases (CVDs) (Box 4.16.1). Rheumatoid arthritis (RA) is the most common CVD associated with PUK, likely due to its high prevalence in the population (affecting 2.5%–3% of adults). Granulomatosis with polyangiitis (GPA) (formerly known as Wegener's granulomatosis) and other antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides, although relatively rare, are an important cause of PUK. An associated scleritis may occur in a significant portion of patients, the presence of which, especially when necrotizing, suggests an active vasculitic process.<sup>1</sup> In general, patients with rheumatoid arthritis (RA)-associated PUK usually have an established systemic diagnosis with evidence of advanced disease (subcutaneous nodules, vasculitis, cardiac involvement<sup>15</sup>) or clinical findings supportive of the diagnosis of RA. However, in up to 25% of patients, the PUK may be the initial presenting feature of potentially lethal undiagnosed systemic vasculitis,<sup>1</sup> highlighting the importance of a thorough systemic evaluation. Additionally, in patients with scleritis, the additional presence of PUK portends poor ocular and systemic prognosis.<sup>14</sup>

### BOX 4.16.1 Etiologies of PUK

#### Ocular Noninfectious

- Idiopathic
- Acne rosacea (ocular)
- Mooren's ulcer
- Traumatic, postoperative (may be a presenting feature of a systemic autoimmune disorder)
- Exposure/neuroparalytic keratopathy

#### Ocular Infectious

- Bacterial (*Staphylococcus*, *Streptococcus*, *Gonococcus* [rare])
- Viral (herpes simplex and herpes zoster)
- Amebic (*Acanthamoeba*)
- Fungal

#### Systemic Noninfectious

##### Collagen Vascular Diseases/Vasculitis

- Rheumatoid arthritis (common)
- Antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides
- Granulomatosis with polyangiitis (previously Wegener's granulomatosis) (relatively common)
- Polyarteritis nodosa (less common)
- Microscopic polyangiitis (MPA) (less common)
- Churg–Strauss syndrome (less common)
- Relapsing polychondritis (uncommon)
- Systemic lupus erythematosus (less common)
- Progressive systemic sclerosis/scleroderma (rare)
- Giant cell arteritis (very rare)

##### Other Systemic Autoimmune

- Cicatricial pemphigoid (especially with trichiasis) (rare)
- Inflammatory bowel disease (very rare)
- Sarcoidosis (very rare)
- Sjögren's syndrome
- Leukemia/malignancy (very rare)
- Inflammatory bowel disease (usually associated with a nonulcerative peripheral keratitis)
- Giant cell arteritis (rare)

#### Systemic Infectious

- Gonorrhea
- Bacillary dysentery
- Tuberculosis
- Borreliosis (Lyme disease—very rare)
- Varicella zoster
- Helminthiasis

## DIFFERENTIAL DIAGNOSIS

PUK is a clinical diagnosis and identifying the cause is paramount for the proper management. Infections may cause peripheral corneal inflammation and ulceration and must be rapidly recognized (see Box 4.16.1) because therapy is markedly different from that for PUK caused by autoimmune disease-mediated conditions (Fig. 4.16.3). However, patients with autoimmune disease-associated PUK may become secondarily infected, and thus infectious causes must always be excluded in the initial workup. Local inflammatory causes include *Staphylococcus* marginal ulcers, which begin with an infiltrate adjacent to the limbus separated by a characteristic clear zone with progression to ulceration and rosacea-associated blepharoconjunctivitis and which may result in a peripheral keratitis with or without a clear zone.

Mooren's ulcer is a specific form of unilateral or bilateral PUK that is characterized by a chronic, usually severely painful, single or multicentric corneal ulcer that begins in the periphery adjacent to the sclera with a characteristic steep, undermined, or overhanging central margin and occasionally infiltrated leading central border without associated scleritis<sup>16</sup> (see also Chapter 4.17).

Noninflammatory cause of thinning of the peripheral cornea, as seen with Terrien's marginal degeneration, pellucid marginal degeneration, and marginal furrow can be distinguished from PUK because of lack of inflammation and typically an intact epithelium.

**Fig. 4.16.3** Herpes Simplex Virus Peripheral Keratitis (Polymerase Chain Reaction Positive) (A). Image of the Same Patient With Fluorescein (B).

## DIAGNOSTIC AND ANCILLARY TESTING

A thorough history must be obtained about any previous history of ocular infections, including ocular and nonocular herpetic disease, contact lens wear, and current and previous medication, trauma, or surgery. Because PUK may be an initial or presenting feature of an underlying systemic collagen vascular disease (see [Box 4.16.1](#)), a comprehensive review of systems should be obtained, with particular questions related to various systems involved in the systemic diseases associated with PUK. A complete ophthalmic examination to exclude local pathologies is critical. A comprehensive physical examination should be performed by the appropriate specialist when an underlying systemic process is suspected.

Laboratory tests are listed in [Box 4.16.2](#). Appropriate testing should exclude infectious etiologies.

## TREATMENT

### Medical Treatment

Prior to therapy, infectious causes need to be excluded by the appropriate culture techniques, with antimicrobial therapy administered if infections are suspected. Prophylactic topical antibiotics often are used to prevent secondary infections.

In milder, unilateral cases of peripheral ulcerative keratitis (and typically when not associated with a systemic CVD), topical corticosteroids may be considered as initial therapy (at times combined with conjunctival resection with the latter being not only therapeutic but of potential diagnostic value) ([Fig. 4.16.4](#)). Although topical corticosteroids may be a

**Fig. 4.16.4** Peripheral Ulcerative Keratitis (PUK) Following Conjunctival Resection for Diagnostic and Therapeutic Purposes. Same Patient as in [Fig. 4.16.2](#).

### BOX 4.16.2 Workup of Peripheral Ulcerative Keratitis (Noninfectious)

- CBC
- RF
- Anti-CCP
- c-ANCA and p-ANCA
- ESR and CRP, CIC
- Urine analysis
- Radiographs
  - Chest
  - Sinus

ANCA, antineutrophil cytoplasmic antibody; anti-CCP, anti-cyclic citrullinated protein antibodies; c-ANCA, antineutrophil cytoplasmic antibodies/cytoplasmic staining pattern; CBC, complete count; CIC, circulating immune complexes; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; MPA, microscopic polyangiitis; GPA, granulomatosis with polyangiitis; p-ANCA, antineutrophil cytoplasmic antibodies/perinuclear staining pattern; RF, rheumatoid factor.

useful adjunct in milder cases of RA-associated PUK, it is not effective in GPA, microscopic polyangiitis, Churg–Strauss syndrome, and polyarteritis nodosa. In these cases, topical corticosteroids may promote progression and even enhance perforation and thus must be used judiciously.<sup>17</sup> Topical cyclosporin A may have some benefit as an adjunct when combined with the appropriate systemic therapy.

Systemic corticosteroids, in the form of oral prednisone 1 mg/kg/day, are very commonly used for the acute management of more severe cases of PUK. If progression occurs, pulsed methylprednisolone (0.5–1.0 g) for three consecutive days may be effective.<sup>18</sup> However, corticosteroids alone may be inadequate to control the progressive ocular disease process or impact the systemic morbidity and mortality in patients who have active systemic autoimmune disease. The prolonged use of corticosteroids also will result in significant systemic side effects often necessitating alternative corticosteroid-sparing immunosuppressive agents.

In severe cases of PUK, where there is progression and threat of perforation, therapy with systemic corticosteroids at doses up to 100 mg/day combined with immunosuppressive agents must be used. The presence of vasculitis is a key factor in deciding if systemic immunosuppressive therapy will be required (with concurrent associated scleritis highly suggestive of an active vasculitis process). Other indications for systemic immunosuppressive therapy are noted in [Box 4.16.3](#).

Various systemic immunosuppressive agents, such as methotrexate, azathioprine, mycophenolate mofetil, cyclosporin A, and cyclophosphamide, have demonstrated some clinical efficacy for inflammatory eye disease, including PUK<sup>19,20</sup> ([Table 4.16.1](#)). Although the drugs chosen are somewhat nonspecific and the choices are limited by the lack of prospective clinical trials, accumulated data suggest that cyclosporin A with dosages in the range of 2.5 mg/kg/day may be a reasonable initial choice for idiopathic PUK, especially if nephrotoxicity is not a concern. It may be switched to or combined with an alternative immunosuppressive agent if

**TABLE 4.16.1 Immunomodulatory/Immunosuppressive Therapy in PUK**

Drug	Disease Indication	Dosage
Azathioprine	RA, GPA, and RP (second choice)	2 mg/kg/day
Cyclophosphamide	GPA and PAN (first choice), RA (severe), RP (second choice)	2 mg/kg/day
Methotrexate	RA (first choice), maintenance for GPA	10–25 mg/wk PO or SC
Cyclosporine A	Idiopathic (first choice), RA, RP (second choice)	2–2.5 mg/kg twice daily
Mycophenolate mofetil	Alternative to azathioprine	1 g twice daily, with maximum of 1.5 g twice daily
<b>Biological Agents</b>		
<b>Anti-TNF</b>		
Infliximab	RA, Crohn's disease	For RA 3 mg/kg IV infusion at 0, 2, 6 weeks then every 8 weeks For Crohn's disease, 5 mg/kg 0, 2, and 6 weeks; then every 8 weeks Dosage may be increased interval of treatment reduced
Adalimumab	RA, Crohn's disease	40 mg SC every 4 weeks
Anti-CD22 (B cell) Rituximab	RA, GPA, MPA	For GPA 375 mg/m <sup>2</sup> once weekly for 4 weeks For RA two 1000 mg IV infusion separated by 2 weeks, preceded by 30 minutes with 100 mg of IV prednisolone Dosage may be increased interval of treatment reduced

RA, rheumatoid arthritis; WG, Wegener's granulomatosis; GPA, granulomatosis with polyangiitis; RP, relapsing polychondritis; PAN, polyarteritis nodosa; PO, per os (oral); PUK, peripheral ulcerative keratitis; SC, subcutaneous; IV, intravenous.

### BOX 4.16.3 Indications for Systemic Immunomodulatory Therapy in Peripheral Ulcerative Keratitis (PUK)

1. PUK associated with a potentially lethal systemic disease, such as rheumatoid arthritis, Wegener's granulomatosis, relapsing polychondritis, polyarteritis nodosa
2. PUK with associated scleritis
3. Bilateral Mooren's ulcer
4. Disease progression despite local conjunctival resection and tectonic procedures (e.g., tissue adhesive)

inadequate response or progression occurs. However, if the PUK is found to be associated with a specific systemic CVD, then immunosuppressives proven to be effective for the treatment of the systemic disease should be considered. In cases of GPA-associated PUK (or with more severe or rapidly progressive PUK associated with other CVDs), especially when accompanying necrotizing scleritis exists, cytotoxic immunosuppressives, such as cyclophosphamide (2 mg/kg orally), together with corticosteroids (oral or pulse intravenous) are the first-line therapy, with oral or subcutaneously injected methotrexate useful for maintenance.

The role of biological agents, such as the anti-tissue necrosis factor (TNF) and anti-B cell monoclonal antibodies, in the treatment of PUK has become more accepted because of more cumulative experience in the form of case reports, small series, personal experiences of those who treat severe inflammatory eye disease<sup>21–24</sup> and because of their well-established efficacy in the treatment of systemic inflammatory diseases, such as RA, GPA, spondyloarthropathies, inflammatory bowel disease, and other systemic vasculitides. A recent study found systemic rituximab more effective in controlling GPA-associated progressive PUK (11 of 11) than cyclophosphamide (5 of 10).<sup>25</sup> However, the high cost of these drugs and the uncertain long-term side effects may be limiting more widespread use. Systemic therapy should be continued for a period of at least 6 months to 1 year after initial control of inflammation has been achieved with proper monitoring for drug-related side effects. Lymphoma and other malignancies, some fatal, have been reported in children and adolescent patients treated with

TNF blockers. Long-term close monitoring is required as disease recurrence and relapse may occur (especially when associated with systemic vasculitis), requiring immediate re-initiation of systemic therapy.<sup>25,26</sup>

A physician with expertise in the appropriate use and proper monitoring of potential complications should administer the immunosuppressive regimen.

## Surgical Treatment

Surgical treatments may be required in the management of PUK and to maintain the integrity of the globe but are typically adjunctive because when used alone, they will not influence the underlying immunological process and the potential lethal systemic consequences. Conjunctival resection<sup>27,28</sup> may temporarily remove the local cellular mediators and collagenases important in progression of the disease process and may be of great diagnostic help; for example, identification of significant microangiitis would support the use of immunosuppressive therapy (see Fig. 4.16.4). However, as a therapeutic adjunct, it is limited to localized unilateral disease without any associated systemic inflammatory disorder.

Cyanoacrylate adhesive<sup>29</sup> in conjunction with immunosuppressive therapy may be used in patients with impending perforation and may delay the need for tectonic corneal surgery. Conjunctival flaps, amniotic membrane grafts,<sup>30</sup> and tectonic lamellar and penetrating corneal grafts<sup>31</sup> may be required to preserve the integrity of the globe, with a guarded prognosis,<sup>32</sup> and should be used in conjunction with systemic immunosuppressive therapy.

## COURSE AND OUTCOME

The course, duration, and outcome are variable and dependent on the underlying cause of PUK and on prompt and appropriate management. Many patients with mild or moderate PUK may maintain good vision if the inflammatory process is rapidly controlled. The prognosis is more guarded when PUK is associated with a systemic CVD. Significant visual loss and ocular morbidity may develop with corneal perforation. Both ocular prognosis and systemic prognosis are more guarded when concomitant scleritis exists, especially necrotizing scleritis. Even in cases where no systemic condition can be identified initially, continued surveillance should be maintained. In up to 25% of cases, a systemic disorder is recognized after the presentation of the eye disease. Failure to identify and concurrently treat an associated systemic inflammatory disease may lead to significant ocular and systemic morbidity and even mortality. Systemic immunomodulatory therapy is required when progression occurs with local therapy, an association with collagen vascular diseases, or bilateral Mooren's disease.

Noninfectious Keratitis

Roshni A. Vasaiwala, Charles S. Bouchard

4.17

**Definition:** Corneal inflammation with no known infectious etiology.

Key Feature

- Diverse group of diseases with corneal inflammation as the common feature.

Associated Feature

- Systemic inflammatory disease.

INTRODUCTION

In this chapter, well-characterized clinical entities that, to date, have no known infectious cause are presented. A list of noninfectious corneal inflammatory diseases is given in Table 4.17.1.<sup>1</sup>

The term *noninfectious keratitis* describes a wide range of entities with some common clinical features and of no known infectious etiology. These include focal or diffuse inflammation, abnormal epithelial healing, and neovascularization.<sup>1</sup> These findings result, in part, from the proximity of the peripheral cornea and its access to the afferent and efferent pathways of the limbal vasculature. Clinical symptoms associated with noninfectious keratitis include photophobia, pain, redness, and decreased visual acuity. Visual loss may result from an irregular surface, corneal opacity, or altered topography from corneal thinning. Approaches to management include (1) determination of the specific cause; (2) promotion of epithelial healing; (3) limitation of ulceration and stromal loss; and (4) support of repair.<sup>1</sup> Both local and systemic routes of therapy may be necessary for optimal outcomes.

THYGESON’S SUPERFICIAL PUNCTATE KERATITIS

Epidemiology and Pathogenesis

Thygeson’s superficial punctate keratitis (TSPK) is a bilateral, epithelial keratitis of unknown cause and was first described by Phillips Thygeson in 1950.<sup>2</sup> It is characterized by an insidious onset of focal corneal epithelial inflammation with a pattern of exacerbations and remissions. The disease can last from 1 month to 24 years, with an average duration of 3.5 years. TSPK usually begins in the second and third decades (mean age, 29 years), with a range of 2.5–70 years. No clear gender predilection exists, although a female preponderance has been suggested.

No established cause for this disease is known, and no clear trigger mechanisms or associated systemic illnesses have been identified. The clinical manifestations of TSPK resemble those of viral keratitis. There are conflicting reports about a viral cause.<sup>3,4</sup>

The characteristic exacerbations and remissions of the disease may be caused by an altered immune response to an unknown exogenous or endogenous antigen. A genetic predisposition may be present because some patients demonstrate an increase in human leukocyte antigen

(HLA)-Dw3 and HLA-DR3 expression, both of which are HLA loci associated with immune response genes.<sup>5</sup>

Ocular Manifestations

The lesions of TSPK typically appear in the central cornea as small, round or oval, discrete, granular, white-gray, fine, dot-like intraepithelial opacities. The number of lesions ranges from 3–40, and occasionally the lesions appear stellate (Fig. 4.17.1). Stromal edema and associated cellular

**Fig. 4.17.1** Corneal punctate lesions characteristic of Thygeson's superficial punctate keratopathy. These typically occur in a noninflamed eye. (Courtesy Joel Sugar, MD.)

**Fig. 4.17.2** A Patient Who Has Thygeson's Superficial Punctate Keratopathy. Slit-lamp appearance of the fine subepithelial haze and relative lack of corneal inflammation between lesions are shown.

infiltration generally are absent (Fig. 4.17.2). Subepithelial opacities occur in 44% of patients. TSPK is bilateral in 96% of patients. Conjunctival inflammation is absent.

Active lesions are resistant to mechanical removal and appear elevated following fluorescein staining with negative staining. During remissions, the epithelium is flat and without stain over the previous areas of keratitis. Although most lesions are central, peripheral lesions do occur and may be associated with delicate, peripheral vascularization in chronic cases.

Symptoms include tearing, foreign body sensation, photophobia, and burning. Visual acuity may be decreased by the subepithelial opacities but generally returns to normal following resolution of the keratitis.

## Diagnosis

Thygeson<sup>2</sup> outlined five characteristic features of TSPK: (1) chronic, bilateral punctate inflammation; (2) long duration, with remissions and exacerbations; (3) healing without significant scarring; (4) absent clinical response to topical antibiotics; and (5) striking symptomatic and clinical response to topical corticosteroids.

The diagnosis of TSPK generally can be made from the clinical history, results of slit-lamp examination, and the unusually rapid response to topical corticosteroids. No specific systemic associations have been reported for this disease.

## Differential Diagnosis

One of the most characteristic features of TSPK is its lack of associated conjunctival inflammation. All the other disease entities in Box 4.17.1 have either obvious associated features or signs of local or diffuse conjunctival inflammation.

### BOX 4.17.1 Differential Diagnosis of Thygeson's Superficial Punctate Keratitis

- Herpes simplex keratitis
- Other viral keratitis (adenovirus)
- Molluscum contagiosum keratitis
- Exposure keratitis
- Blepharokeratitis
- Neurotrophic keratopathy
- Staphylococcal keratitis
- Traumatic keratopathy
- Dry eye disease
- Acanthamebic keratitis (early)

## Pathology

Corneal scrapings of the lesions demonstrate atypical and degenerated epithelial cells and a mild mononuclear and polymorphonuclear cell infiltrate. Confocal microscopy has demonstrated the accumulation and aggregation of Langerhans' cells in the basal cell layer of the corneal epithelium in association with decreased density of the subepithelial nerve plexus of affected eyes, suggesting an immune response.<sup>6</sup>

## Treatment

Topical low-dose corticosteroids decrease the signs and symptoms of TSPK and probably are most effective during acute exacerbations. The course of the disease may be prolonged with the chronic use of corticosteroids. Topical 2% cyclosporine or tacrolimus<sup>7</sup> have been effective in the management of TSPK, with few side effects.<sup>8</sup> Therapeutic bandage contact lenses may be used to improve visual acuity and improve comfort in more symptomatic patients. The use of antiviral agents has been evaluated, but no convincing evidence exists that they are effective.<sup>9</sup> Photorefractive keratectomy may reduce the recurrences in the central ablated cornea, suggesting that some unknown inflammatory signal may reside in the superficial corneal stroma.<sup>10,11</sup>

## Course and Outcome

Most patients with TSPK recover completely with no loss of visual acuity, although up to 44% may be left with faint subepithelial opacities.

## SUPERIOR LIMBIC KERATOCONJUNCTIVITIS OF THEODORE

### Epidemiology and Pathogenesis

Superior limbic keratoconjunctivitis (SLK) is a chronic, focal, ocular surface disease characterized by episodes of recurrent inflammation of the superior cornea and limbus, as well as of the superior tarsal and bulbar conjunctiva.<sup>12</sup> It occurs primarily in adults age 30–55 years and is more common in women (3:1). It typically is bilateral, but unilateral disease may occur.

Although the pathophysiology is unclear, mechanical trauma from tight upper lids or loose redundant conjunctiva could lead to the known disruption of normal epithelial development.<sup>13</sup> This mechanical hypothesis is supported by the increased lid apposition in patients with exophthalmic thyroid disease, who are known to have an increased incidence of SLK,<sup>14</sup> as well as increased lubrication being an effective treatment modality.<sup>15</sup>

### Ocular Manifestations

The classic sign of SLK is bilateral local hyperemia of the superior bulbar conjunctiva (Fig. 4.17.3), which also appears keratinized, thickened, and redundant. The opposing superior palpebral conjunctiva demonstrates a delicate papillary reaction with associated hyperemia. Fine fluorescein or Rose Bengal punctate staining usually is present. Keratoconjunctivitis sicca occurs in 25%–50% of patients and must be evaluated in all patients with SLK.<sup>14</sup> A fine filamentary keratitis of the superior cornea and limbus may be present (Fig. 4.17.4). A delicate superior corneal pannus suggests more long-standing disease.

**Fig. 4.17.3 Superior Limbic Keratoconjunctivitis.** Slit-lamp appearance of focal superior bulbar conjunctival injection is shown with Rose Bengal staining.

**Fig. 4.17.4 Superior Limbic Keratoconjunctivitis.** Slit-lamp appearance of superior filamentary keratitis is shown.

Characteristic symptoms include a gradual onset of burning, tearing, foreign body sensation, mild photophobia, and sometimes mucus discharge. Patients may notice pain and decrease in vision if the filamentary component is severe or occurs within the visual axis.

## Diagnosis

The diagnosis of SLK is made from the history of irritation, photophobia, and the specific pattern of superior corneal and conjunctival inflammation and staining. Superior filamentary keratitis supports the diagnosis.

## Differential Diagnosis

The differential diagnosis of SLK is shown in [Box 4.17.2](#). Filamentary keratitis may occur in up to 40% of patients with SLK. The distribution of filaments on the upper cornea and limbus may help differentiate SLK from dry eye disease (DED), in which filaments occur more typically on the lower half of the cornea.

An inflammatory condition associated with soft contact lens wear may resemble SLK. Although many signs and symptoms of this contact lens-related SLK are similar to those of SLK of Theodore, filaments are usually absent, vision may be decreased (unusual in SLK), and no female predilection or associated thyroid dysfunction exists. More importantly, symptoms generally improve with discontinuation of contact lens wear. Contact lens-induced keratoconjunctivitis may be a more appropriate term for this entity, with SLK reserved for the specific condition described by Theodore.<sup>12</sup>

SLK-like inflammation can occur in patients with chronic ocular graft-versus-host disease (GVHD).<sup>16</sup> These patients present with the typical signs of SLK, including conjunctival injection and staining of the superior conjunctiva and cornea. They also tend to show good response to the

### BOX 4.17.2 Differential Diagnosis of Superior Limbic Keratoconjunctivitis of Theodore

#### Keratoconjunctivitis With Filaments

- Ptosis/lid occlusion
- Keratoconjunctivitis sicca
- Neurotrophic keratitis
- Herpes simplex epithelial keratitis
- Recurrent corneal erosion
- Trauma
- Bullous keratopathy
- Medicamentosa

#### Keratoconjunctivitis Without Filaments

- Keratoconjunctivitis induced by contact lens
- Limbal vernal keratoconjunctivitis
- Phlyctenulosis
- Thygeson's superficial punctate keratitis

common treatments for SLK. If this type of inflammation goes undiagnosed in patients with chronic GVHD, they can develop limbal stem cell deficiency, scarring, and loss of vision.<sup>16</sup>

## Systemic Associations

Systemic associations include thyroid disease and collagen vascular disease. In one study in a referral university setting, 65% of patients who had SLK were found to also have thyroid dysfunction.<sup>14</sup> Of those patients who had SLK and thyroid disease, 90% had ophthalmopathy, and 49% had severe thyroid disease necessitating orbital decompression. SLK is a strong negative prognostic factor for patients who have thyroid disease.<sup>14</sup>

## Pathology

The superior bulbar conjunctiva demonstrates keratinization of the epithelium with intracellular accumulation of glycogen and abnormal chromatin. A predominantly polymorphonuclear infiltrate occurs. Acanthosis, squamous metaplasia, dyskeratosis, balloon degeneration of nuclei, and decreased goblet cell density, and conjunctival stromal edema occur. Upregulation of transforming growth factor- $\beta_2$  and tenascin support an increase in mechanical stress.<sup>15</sup> Altered expression of cytokeratins also suggests an abnormality of epithelial differentiation.<sup>17</sup> One study found elevated levels of matrix metalloproteinases (MMP-1 and MMP-3) in surgical specimens from patients with SLK compared with controls, suggesting a possible role of MMP imbalance in the pathogenesis.<sup>18</sup>

Changes in the superior palpebral conjunctiva are somewhat different, with an increase in polymorphonuclear neutrophil leukocytes, lymphocytes, and plasma cells. The overlying epithelium contains hypertrophic goblet cells.

## Treatment

Because a large proportion (25%–50%) of patients who have SLK also have DED, care must be taken to treat any concurrent aqueous tear deficiency with unpreserved tears and, if indicated, punctal occlusion.<sup>19</sup> Associated blepharitis also must be managed. Any lid surgery, especially ptosis repair, should be evaluated carefully because possible exacerbation of SLK may be caused by lid tightening and possible secondary exposure.

Surgical approaches to treatment involve the destruction or resection of the presumed abnormal conjunctival epithelium. Simple resection or recession of the conjunctiva with Tenon's capsule can be very effective. Use of cryotherapy and thermocautery has been reported, with symptom improvement in 75% of patients treated with the latter.<sup>20</sup>

Bandage contact lenses and pressure patching have been used to manage severe symptoms of photophobia, ocular discomfort, and associated filamentary keratitis. SLK often recurs, however, after lens wear has been discontinued.

Topical hypertonic saline solutions may help reduce the excessive mucus production and associated filaments. *N*-acetylcysteine (Mucomyst), in 10%–20% solution, may offer relief in severe cases. Topical cromolyn or lodoxamide may offer symptomatic relief of itching.

The chronic use of topical corticosteroids should be discouraged. Topical cyclosporine A and autologous serum have been reported to be effective in

**Fig. 4.17.5 Acute Mooren's Ulcer.** Peripheral thinning and an overlying epithelial defect are present in an inflamed eye. (Courtesy Joel Sugar, MD.)

**Fig. 4.17.6 Mooren's Ulcer.** Peripheral thinning is present in a relatively quiet eye in this patient who had a history of Mooren's ulcer, now in remission.

some cases.<sup>21,22</sup> Topical vitamin A eyedrops may be variably effective during inflammatory periods.<sup>23</sup> Topical tacrolimus 0.03% ointment has been successful in the treatment of cases refractory to the above treatment modalities.<sup>24</sup> Topical rebamipide, a medication initially used to increase gastric mucosa mucin, has been shown to improve SLK in patients with thyroid disease.<sup>25</sup>

## Course and Outcome

Many of the proposed therapies have been effective, and the overall prognosis is excellent because the visual axis usually is not affected.

## MOOREN'S ULCER

### Epidemiology and Pathogenesis

Mooren's ulcer, a rare, chronic, painful, peripheral ulcerative keratitis (PUK), was first described in detail as a clinical entity by Mooren in 1867.<sup>26</sup> Two clinical types of primary Mooren's ulcer have been described.<sup>27</sup> The limited type is typically unilateral, occurs in the fourth decade or later, and is more responsive to local surgical and medical therapy. The second type, which is more resistant to systemic immunosuppression, involves a bilateral, painful, relentless, progressive destruction of the cornea, usually in younger individuals (third decade), many of whom are of African descent.

The pathogenesis of Mooren's ulcer is unknown but appears to involve an autoimmune reaction against a specific target molecule in the corneal stroma, which may occur in genetically susceptible individuals.<sup>28</sup> Both cellular and humoral mechanisms have been postulated.<sup>29</sup> The conjunctival epithelium demonstrates increased levels of several inflammatory mediators.<sup>30</sup>

Interestingly, there have been several reported cases of Mooren's ulcer in patients with concurrent hepatitis C whose corneal inflammation responded to systemic interferon- $\alpha$  (IFN- $\alpha$ ).<sup>31</sup> These cases suggest a common antigenic source.<sup>32</sup>

### Ocular Manifestations

Mooren's ulcer is characterized by a progressive, crescentic, peripheral corneal ulceration that is slightly central to the corneoscleral limbus. It is associated with a characteristic extensive, undermined, "overhanging" edge (Fig. 4.17.5). It progresses with an anterior, stromal, yellow-white infiltrate at the advancing margin. An overlying epithelial defect then develops. Progressive stromal melting follows, which affects first the deeper and subsequently the anterior stroma. The ulcer progresses circumferentially and centrally. A re-epithelialized, conjunctivalized, thinned cornea remains. Patients in whom Descemet's membrane has a minimal overlying stroma may be predisposed to perforation either spontaneously or following minor trauma.

In the more aggressive form of Mooren's ulcer, the inflammation may affect the entire cornea and perilimbal tissue. Perforation is not uncommon

in this form, occurring in about one third of patients. Associated cataract, secondary glaucoma, and uveitis may be seen.

Chronic Mooren's ulcer ultimately results in a central island of hazy stromal tissue with severe peripheral thinning (Fig. 4.17.6). No scleral involvement occurs, although associated conjunctival and episcleral inflammation may be seen. No clear zone exists between the ulcer and the limbus, which distinguishes Mooren's ulcer from other forms of PUK. Visual loss as a result of severe, irregular corneal astigmatism and scarring is common.

### Diagnosis

Mooren's ulcer is, by definition, not associated with any systemic abnormality, except for the occasional association with hepatitis C. Collagen vascular disease must be excluded. Patients should also be tested for hepatitis C virus.<sup>32</sup> Patients who have other systemic diseases, including leukemia, pyoderma gangrenosum, and syphilis, also may develop PUK.<sup>33</sup>

Patients complain of severe ocular pain, photophobia, and tearing. The overlying epithelium in other degenerative corneal lesions remains intact.

### Differential Diagnosis

Although there are many other causes of PUK (Box 4.17.3), Mooren's ulcer is an unusual and severe inflammatory disease without known associated systemic disease (except perhaps hepatitis C).

### Pathology

Three zones of corneal involvement have been described. The superficial stroma contains lymphocytes, plasma cells, polymorphonuclear leukocytes, disrupted collagen lamellae, and neovascular elements. The mid-stroma demonstrates an increase in the number of fibroblasts, and the deep stroma is infiltrated primarily by macrophages. The epithelial basement membrane is disrupted at the leading edge, and the characteristic infiltrate contains primarily neutrophils.

Conjunctival resections from patients with Mooren's ulcer demonstrate increased levels of inflammatory mediators, including vascular cell adhesion molecule-1 (VCAM-1), very late activation-4, intercellular adhesion molecule-1 (ICAM-1), and lymphocyte function-associated antigen-1.<sup>27</sup>

### Treatment

A stepladder approach to manage this aggressive disease has been proposed. This includes local, systemic, and surgical therapies.<sup>34</sup> Initial treatment should begin with topical corticosteroids, followed by conjunctival resection if the inflammation is not controlled. Topical cyclosporine drops and tacrolimus ointment have been effective in some cases.<sup>35</sup> In addition, bandage contact lenses, as well as amniotic membrane transplantation,<sup>36</sup> may reduce discomfort and promote epithelial healing in refractory cases. Topical administration of IFN- $\alpha$  may be helpful.<sup>37</sup>

Systemic immunosuppression with cyclophosphamide followed by azathioprine may be initiated if treatment with conjunctival resection fails. Systemic immunosuppressive treatment of the more aggressive bilateral disease has included corticosteroids, cyclosporine, methotrexate, and infliximab.<sup>34,38,39</sup> Systemic IFN- $\alpha_{2b}$  has been effective in the treatment of patients who are positive for hepatitis C virus and have Mooren's ulcer.<sup>31</sup>

Systemic workup for vasculitis or collagen vascular disease is mandatory for patients who are suspected of having Mooren's ulcer. The primary goal of therapy is to slow the severe progression of the corneal loss, although 50% of cases may be unresponsive to all medical therapy.<sup>34</sup>

Small perforations can be managed with cyanoacrylate adhesive but large perforations require lamellar or full-thickness keratoplasty.

Surgical management for visual rehabilitation is a challenge as penetrating keratoplasty is usually associated with disease recurrence, graft rejection, and melting.

**Course and Outcome**

Most patients who have unilateral disease respond fairly well to topical corticosteroids and conjunctival resection. For more severe bilateral cases, the prognosis is poor.

**NEUROTROPHIC KERATITIS****Epidemiology and Pathogenesis**

Lesions of the fifth cranial nerve from the trigeminal nucleus to the cornea may lead to abnormalities of the normal corneal sensation and trophic stimulation. The trophic ulceration that results leads to abnormal repair of corneal epithelium secondary to increased apoptosis and reduced proliferation of epithelial cells and reduced reflex tearing.<sup>40</sup> Normally, a bidirectional interaction occurs between epithelial cells and nerve endings. Adrenergic stimulation leads to increased cyclic adenosine monophosphate, which inhibits mitosis.<sup>41</sup> Cholinergic stimulation leads to increased cyclic guanosine monophosphate, which increases cell turnover.<sup>41</sup> Substance P may play a role in normal and abnormal epithelial cell turnover.<sup>41–43</sup> Disruption of the sensory and sympathetic pathways is thought to lead to decreased cell division.<sup>41</sup> Cells, therefore, fail to resist the effects of trauma (microtrauma) and desiccation, which normally lead to reflex tearing.<sup>44,45</sup> Increased inflammatory cytokines, such as interleukin-6 (IL-6), may play a role in nerve degeneration in herpes simplex infection.<sup>46</sup>

Varicella zoster keratitis (8% of patients) and herpes simplex keratitis are the most common causes of neurotrophic keratitis. In addition to traumatic damage to the ophthalmic branch of the fifth cranial nerve following various surgical procedures, stroke, irradiation to eye or adnexa, aneurysm, multiple sclerosis, toxic chemical reactions, and brainstem hemorrhages may lead to trigeminal dysfunction and corneal ulceration.

**Fig. 4.17.7 Neurotrophic Keratitis.** Slit-lamp appearance in a patient who developed a paracentral epithelial defect with minimal subepithelial inflammation.

**Fig. 4.17.8 Neurotrophic Keratitis.** Slit-lamp appearance in a patient who has a partial seventh nerve palsy. He was treated with ciprofloxacin and developed deposits of the antibiotic on the cornea.

**Ocular Manifestations**

Mackie<sup>47</sup> characterized three stages of neurotrophic keratitis. Stage I includes an often subtle irregular corneal surface, which later develops into an easily recognized punctate keratitis. Stage II is characterized by a frank epithelial defect, which typically is associated with mild anterior stromal edema and inflammation (Fig. 4.17.7). Folds in Descemet's membrane often develop. The epithelium at the edges of the defect tends to be characteristically "heaped up" or "rolled" with grayish, swollen epithelium. The ulcer usually is found in the lower, exposed, paracentral cornea and is generally oval in shape (Fig. 4.17.8). Stage III involves stromal melting and occasionally perforation. Characteristic symptoms include red eye, mild foreign body sensation, blurred vision, and lid edema.

**Diagnosis**

A history of surgery, irradiation, stroke, or decreased hearing should be established, in addition to a previous history of red eye. Decreased corneal sensation is evident with or without a decrease in conjunctival sensation. Decreased aqueous tear production may be associated with neurotrophic keratopathy.<sup>48</sup>

**Differential Diagnosis**

The differential diagnosis of decreased corneal sensation is given in Box 4.17.4. Herpes simplex and herpes zoster are the most common causes, and each has a characteristic initial clinical presentation. Topical drug toxicity, contact lens wear, dry eye, chronic exposure, and limbal stem cell deficiency may contribute to decreased corneal sensation. Finally, diabetes is a well-described cause of neurotrophic keratitis and may result in epithelial healing problems.

### BOX 4.17.4 Differential Diagnosis of Decreased Corneal Sensation

- Lesions to the ophthalmic division of the trigeminal nerve
  - Surgery
  - Acoustic neuroma
  - Trauma
- Infectious disease
  - Herpes simplex
  - Herpes zoster
- Contact lens wear
- Diabetes
- Topical agents
  - Anesthetics
  - Beta-blockers
  - Nonsteroidal anti-inflammatory agents

## Systemic Associations

Diabetic peripheral neuropathy may result in decreased corneal sensation.

## Pathology

Histological changes include acanthotic, hyperplastic epithelium with rete peg formation, stromal scarring, destruction or disruption of Bowman's membrane, and corneal neovascularization. Intracellular edema, irregularity and loss of the epithelial microvilli, and loss of the superficial epithelial cell layer of the cornea may be seen.<sup>40</sup> Epithelial cell attachments are abnormal.

## Treatment

The goals of treatment are to prevent progression of epithelial damage, promote healing, facilitate repair, and prevent recurrence. For mild punctate keratitis, frequent lubrication with unpreserved artificial tear drops and ointment may be effective. Aqueous tear deficiency should be documented. For more severe disease, punctal occlusion may be indicated.

For small epithelial defects, topical ointment with patching may aid in healing. Mild topical corticosteroids may reduce the associated anterior stromal scarring but should be used cautiously.

For persistent epithelial defects and stromal lysis, patching or soft contact lens wear may be tried, but patients usually respond best to lateral or medial tarsorrhaphy (temporary with suture or botulinum-A toxin injection,<sup>48</sup> or permanent). Improved corneal sensation and promotion of epithelial healing may occur following treatment with topical nerve growth factor.<sup>49,50</sup> Collagenase inhibitors play an important role in normal corneal health and repair.<sup>51</sup> Collagenase inhibitors may play a supportive role in the management of neurotrophic keratopathy.<sup>52</sup> Autologous serum may be effective.<sup>53,54</sup> Scleral contact lenses may offer superior long-term efficacy compared with soft bandage lenses.<sup>55,56</sup> Conjunctival flaps may be necessary in severe cases. Corneal perforation can be managed with cyanoacrylate glue and lamellar or penetrating keratoplasty. Amniotic membrane in its sutureless form or secured with or without fibrin glue has been used as an effective patch graft in the management of persistent epithelial defects and deep corneal neurotrophic ulcers refractory to conventional treatment.<sup>57–60</sup> Management of any eyelid abnormality must be aggressive.

## Course and Outcome

Patients with superficial punctate staining should be maintained on daily and evening lubrication. Persistent epithelial defects respond best to tarsorrhaphy. Patients should be advised that neurotrophic ulcerations tend to recur and can be difficult to heal. More severe sterile or infectious ulcers may progress to descemetocoele or perforation.

## TERRIEN'S MARGINAL DEGENERATION

### Epidemiology and Pathogenesis

Terrien's marginal degeneration is a slowly progressive, bilateral, peripheral corneal thinning disorder associated with corneal neovascularization, opacification, lipid deposition, and thinning.<sup>61</sup> High degrees of astigmatism, particularly against-the-rule, may be seen. Up to one third of patients

**Fig. 4.17.9 Terrien's Marginal Degeneration.** Advancing lipid deposits and superficial vascular pannus are present. (Courtesy Joel Sugar, MD.)

may have episcleral or scleral inflammation. Patients typically are 20–40 years of age, although it may present in childhood. It is found more commonly in men than in women (3:1).<sup>62</sup>

The cause is unknown. Two types have been documented. One type occurs primarily in the older population. It usually is asymptomatic and slowly progressive. The other, more inflammatory type characteristically occurs in younger patients and may be associated with episcleritis or scleritis.<sup>63</sup>

## Ocular Manifestations

Terrien's degeneration usually starts superiorly with mild, punctate, sub-epithelial and/or anterior stromal opacities. A clear area exists between the opacities and the limbus. This opacification is followed by the development of a peripheral, superficial, fine vascular pannus, which progresses over years to include a linear subepithelial opacity at the advancing edge. The thinning slowly begins between the limbus and the line of lipid deposition. Typically, a steeper sloping of the cornea occurs at the advancing edge (Fig. 4.17.9), without the overlying edge characteristic of Mooren's ulcer. The thinning progresses circumferentially, but the overlying epithelium typically remains intact. Perforation is rare but may occur. Corneal hydrops has been reported, which may present as a clear intracorneal pocket of aqueous rather than stromal clouding.<sup>64</sup>

Irregular corneal astigmatism from progressive flattening of the vertical meridian and high against-the-rule astigmatism is characteristic. Initial conservative management includes the use of rigid gas-permeable contact lenses. Rarely, Terrien's degeneration may present as a pseudo-ptyerygium with a broad, flat, leading edge that arises in an oblique axis. Underlying corneal thinning should be monitored carefully. Intraocular lenses have been placed successfully through the furrow.

## Diagnosis

Terrien's marginal degeneration is distinguished from other peripheral corneal thinning disorders by the lack of inflammation, presence of superficial vascularization, advancing linear deposition of lipid, lack of epithelial defect, and slow progressive course. Collagen vascular disease should be ruled out. No known systemic disorders occur with Terrien's marginal degeneration.

## Differential Diagnosis

The differential diagnosis of Terrien's marginal degeneration is outlined in Box 4.17.5. Terrien's generally is easy to distinguish from Mooren's ulcer because usually no pain or inflammation occurs. The epithelium is intact, and no overhanging edge exists. Marginal furrow degeneration is bilateral and avascular, with only minimal, if any, thinning.

## Pathology

Bowman's membrane is typically absent or has degenerated (Fig. 4.17.10). Thinning and occasional breaks in Descemet's membrane may be seen. Subepithelial fibrillar collagen degeneration has been demonstrated by

**Fig. 4.17.10 Terrien's Degeneration.** (A) Histological section shows limbus on the left (iris not present) and central cornea to the right. (B) Note the marked stromal thinning, thickened epithelium, and loss of Bowman's membrane on the limbal side.

#### BOX 4.17.5 Differential Diagnosis of Terrien's Marginal Degeneration

- Dellen
- Collagen vascular disease
- Pellucid marginal degeneration
- Sclerokeratitis
- Keratoconjunctivitis sicca
- Staphylococcal marginal keratitis
- Infectious corneal ulcer

light microscopy, and an unknown stromal material in phagocytic cells has been demonstrated by electron microscopy.<sup>63</sup>

### Treatment

Usually no treatment is required, unless perforation or impending perforation occurs. Severe astigmatism may be managed with spectacles or rigid contact lenses. More severe thinning may require crescentic, full-thickness, or lamellar keratoplasty.<sup>65</sup> Eccentric, full-thickness grafts have been performed, with an increase in graft rejection. Recently, case reports have been published in which corneal collagen cross-linking has been used to halt progression and even reverse some of the degenerative changes seen in the condition.<sup>66</sup>

### Course and Outcome

Most patients who have Terrien's degeneration do not progress to corneal perforation and can be managed successfully with glasses or rigid contact

**Fig. 4.17.11** Patient with lax eyelid syndrome (LES)

lenses. Because Terrien's degeneration typically lacks an associated epithelial defect, the risk of infectious keratitis and acute corneal thinning is low.

## LAX EYELID CONDITION, LAX EYELID SYNDROME, AND FLOPPY EYELID SYNDROME

### Epidemiology and Pathogenesis

The term “floppy eyelid syndrome” (FES) was first used in 1981 to describe the association of rubbery, lax upper eyelids with tarsal papillary conjunctivitis seen in young obese men.<sup>67</sup> In 1994, Van den Bosch and Lemji proposed a new classification system to include three related conditions: (1) lax eyelid condition (LEC), describing patients with laxity of the eyelids in patients of any age without conjunctivitis, and not necessarily obese (Figs. 4.17.11 and 4.17.12); (2) lax eyelid syndrome (LES), in patients with LEC who also had chronic conjunctivitis; and (3) floppy eyelid syndrome (FES), in patients who had LES and were obese.<sup>68,69</sup> Eyelid laxity is actually a very common, but overlooked, clinical finding. Ansari reported a high prevalence (54%) of eyelid laxity in the upper or lower eyelids in a veteran's administration population associated with significant ocular surface morbidity.<sup>70</sup>

Obstructive sleep apnea (OSA) is highly prevalent, affecting 34% of men and 17% of women.<sup>71</sup> OSA is a significant public health problem that has remained undiagnosed in 82% of patients and is responsible for \$115 billion dollars in healthcare expenditures annually in the United States.<sup>72</sup> Woog first reported the association between OSA and FES in 1990, with multiple subsequent studies supporting this association.<sup>73–80</sup> Chambe et al. showed that LEC/FES was observed in 15.8% of patients without OSA, 25.8% of patients with OSA, and 40% of patients with severe OSA defined as the apnea-hypopnea index (AHI) score > 30.<sup>77</sup> In another study that included 89 patients with OSA, 16% were found to have FES, and 60.67% were found to have increased eyelid laxity.<sup>79</sup> Additionally, Acar et al. studied 51 patients and monitored the effect of positive airway pressure on clinical symptoms of FES. A significant improvement occurred in FES with

positive airway pressure.<sup>78</sup> A positive correlation between the severity of FES and the severity of OSA has also been reported (Table 4.17.2).<sup>77,78</sup> Robert also reported that LEC itself is strongly associated with OSA.<sup>81</sup>

The pathology of FES was first reported by Netland et al. in 1994, and these authors demonstrated a decreased concentration of elastin in the tarsal plate of patients with FES.<sup>82</sup> This observation was later corroborated by Schlötzer-Schrehardt et al., who demonstrated papillary hyperplasia, keratinization, and subepithelial infiltrate of the tarsal conjunctiva, as well as co-localization of elastin loss with increased presence of matrix metalloproteinase, particularly MMP-7 and MMP-9, in the tarsal conjunctiva and near the ciliary roots, accounting for the clinical sign of lash ptosis (Figs. 4.17.13 and 4.17.14).<sup>83</sup> Ischemia–reperfusion injury has been proposed as the most likely mechanism in LEC.

TABLE 4.17.2 Clinical Findings in Patient With Lax Eyelids and Obstructive Sleep Apnea					
Clinical Finding	Control No OSA	Mild OSA	Moderate OSA	Severe OSA	Sig ( <i>P</i> < .05)

FES, floppy eyelid syndrome; OSA, obstructive sleep apnea; OSDI, ocular surface disease index; TBUT, tear break-up time.

Fig. 4.17.12 Patient with lax eyelid condition (LEC)

The pathophysiology of OSA is complex and incompletely understood.<sup>84</sup> A systemic elastin dysfunction may account for the multisystem changes reportedly associated with OSA. Sériès et al. demonstrated elastin changes in soft palate specimens from patients with OSA undergoing uvulopalatopharyngoplasty (UPPP).<sup>85</sup> Ryan et al. demonstrated selective activation of inflammatory cytokines in an in vitro model of intermittent hypoxia.<sup>86</sup> They further demonstrated that circulating tumor necrosis factor alpha (TNF-α) levels were higher in patients with OSA (2.56 pg/mL; interquartile range [IQR] 2.01–3.42 pg/mL) than in control subjects (1.25 pg/mL; IQR 0.94–1.87; *P* < .001) but normalized with continuous positive airway pressure (CPAP) therapy (1.24 pg/mL; IQR 0.78–2.35 pg/mL; *P* < .002). Circulating neutrophil levels were higher in patients with OSA than in control subjects. Taban et al. found elevated plasma leptin levels in patients with LES. Leptin was proposed to trigger the inflammatory cascade by up-regulating MMP-9, resulting in breakdown of elastin.<sup>87</sup>

Fig. 4.17.13 Clinical grading system for lax eyelids. (From Olver J, Sathia PJ, Wright M. Lower eyelid medial canthal tendon laxity. *Ophthalmology* 2001;108(12):2321–5.)

Fig. 4.17.14 Clinical grading system for lax eyelids. (From Liu DT, Di Pascuale MA, Sawai J, Gao Y, Tseng SCG. Tear film dynamics in floppy eyelid syndrome. *Invest Ophthalmol Vis Sci* 2005;46(4):1188–94.)

Nadeem identified multiple circulating inflammatory factors associated with OSA, including CRP, TNF- $\alpha$ , ICAM, IL-6, IL-8, VCAM, and selectins.<sup>88</sup> Becker reported the elevation of MMP-9 in the tear film of patients with OSA.<sup>89</sup>

## Ocular Manifestations

FES has been associated with a variety of anterior and posterior segment conditions. Anterior ocular findings include keratoconus, ptosis, eyelash ptosis, meibomianitis, blepharitis, and ocular surface disorders including superficial punctate keratitis and chronic conjunctivitis.<sup>90</sup> Patients with FES may present with a variety of symptoms including eye irritation, redness, discharge, pain, swelling of the eyelids, and foreign body sensation.<sup>91</sup> In addition, patients with LEC tend to have a more reactive ocular surface, probably as a result of increased concentration of MMPs, particularly MMP-7 and MMP-9 in the conjunctival epithelium, and also in the tear film.<sup>89</sup> The presence of an increase in MMPs may predispose patients with FES to develop more severe manifestations of a wide variety of ocular surface diseases, including DED; phlyctenular disease; superior limbic keratoconjunctivitis; neurotrophic keratitis; and many other noninfectious ocular inflammatory diseases.

Because of the strong association between LEC and OSA, the diagnosis of FES becomes a critical risk factor for a wide variety of posterior segment neurovascular ocular diseases as well.<sup>77</sup> These include retinal vascular occlusion,<sup>92</sup> nonarteritic anterior ischemic optic neuropathy,<sup>93,94</sup> and glaucoma.<sup>95–98</sup> Kremmer reported a halting of progressive field loss following CPAP treatment in a patient with low-tension glaucoma.<sup>99</sup> OSA and FES should be considered risk factors for those patients, and OSA should be a considered a potential modifiable factor, in addition to IOP, for the development and progression of glaucoma.<sup>100</sup> A positive family history in these patients with OSA can be elicited as well.

## Diagnosis

Several methods exist for diagnosing the presence and severity of lid laxity. Olver et al. described two methods of grading medial canthal tendon laxity.<sup>101</sup> They described the horizontal resting position method, which grades the severity of lid laxity based on the resting position of the lower punctum (Fig. 4.17.15). Normal, or grade 0, was defined as the location of the lower punctum just medial to a vertical line made perpendicular to the upper punctum. Grading ranged from –1 to 6 based on the extent of displacement of the lower punctum at rest. Olver et al. also used the lateral distraction method, which grades the severity of lid laxity on the basis of displacement of the lower punctum laterally from resting position with minimal pressure. They used several anatomical landmarks to describe the degree of lateral displacement including the plica semilunaris, medial corneal limbus, visual axis, and lateral corneal limbus.

Beis et al. defined hyperelasticity as upper lid eversion resulting in exposure of the tarsal conjunctiva for 3 seconds with the eyes in the inferior gaze position.<sup>102</sup> They then separated the severity of FES (LEC) into stages 1 and stage 2, with stage 1 describing tarsal conjunctival exposure lasting less than 6 seconds in the inferior gaze positioning and stage 2 describing exposure for greater than 6 seconds.

Liu et al. separated the severity of FES (LEC) into grade 0 to grade 3 (Fig. 4.17.16).<sup>103</sup> Grade 0 referred to no visibility of the upper eyelid tarsal conjunctiva with eversion and, thus, no floppy eyelid. Grade 1 or mild FES (LEC) described exposure of less than one third of the tarsal conjunctiva. Grade 2 or moderate FES (LEC) included exposure of one third to one half of the tarsal conjunctiva. Grade 3 or severe FES was described as more than one half of the tarsal conjunctiva exposed.

Finally, Robert et al. defined the vertical hyperlaxity of the eyelids as the maximal distance between the palpebral rim and the center of the pupil in primary position after manual traction on the eyelid.<sup>81</sup> They also noted the presence of spontaneous tarsal eversion.

In a general ophthalmology practice, however, most cases of LEC/FES probably are overlooked. This reflects the national statistics of 80% of patients with OSA being undiagnosed. Bouchard et al. supported this conclusion and reported the diagnosis of LEC in only 4% of the 11975 patients with OSA in an academic institution who were seen in the eye clinic over a 5-year period.<sup>100</sup>

## Differential Diagnosis

Because the diagnosis of LEC often is missed, a large population of patients with mild to moderate LEC and LES (with elevated MMP in their tear

**Fig. 4.17.15** Histopathology of eyelid (hematoxylin and eosin stain) (From Schlötzer-Schrehardt U, Stojkovic M, Hofmann-Rummelt C, Cursiefen C, Kruse FE, Holbach LM. The pathogenesis of floppy eyelid syndrome involvement of matrix metalloproteinases in elastic fiber degradation. *Ophthalmology* 2005;112(4):694–704.)

**Fig. 4.17.16** Elastin changes in lax eyelids (Von Gieson stain). (From Schlötzer-Schrehardt U, Stojkovic M, Hofmann-Rummelt C, Cursiefen C, Kruse FE, Holbach LM. The pathogenesis of floppy eyelid syndrome involvement of matrix metalloproteinases in elastic fiber degradation. *Ophthalmology* 2005;112(4):694–704.)

film) has been managed with treatment for DED, with over-the-counter artificial teardrops. In some cases, tear production is decreased, but many have normal tear production and are unresponsive to topical lubricants. Some patients with LES, as in Acar's study, are treated for their associated chronic papillary conjunctivitis, without identifying the eyelid laxity. Associated findings of blepharoptosis, lash ptosis, and ectropion, as well as the meibomianitis that often accompanies the LEC, can be managed separately.<sup>90</sup> Dermatochalasis can mask the LEC as well. Nocturnal lagophthalmos can also be managed.

## Systemic Associations

As mentioned previously, OSA is strongly associated with eyelid laxity. OSA is defined as greater than five apnea/hypopnea events per hour, and severity is graded as mild, moderate, or severe. The respiratory disturbance index (RDI) measures the number of events per hour. The history of snoring and daytime fatigue as well as lax eyelids should prompt suspicion of sleep apnea. Not all patients with OSA have daytime sleepiness and are described as having OSA. Most patients do not remember waking at night during the apneic episode, which makes the diagnosis more difficult. Apnea results in peripheral vasoconstriction and then regional vasodilation of the cerebral and myocardial circulation. Postapneic hyperventilation leads to hypocapnia and peripheral vasodilation. Lack of subsequent vasodilation in the ophthalmic vessels in glaucomatous eyes could then lead to a cerebrovascular “steal” from the blood flow to the optic nerve head. Hypercapnia also increases intracranial pressure and causes metabolic stress and acidosis. As a result of chronic intermittent hypoxia, the increase in sympathetic tone in OSA associated with intermittent hypoxic episodes is thought to result in endothelial damage.<sup>84,86,88</sup> OSA affects the vascular endothelium through oxidative stress, inflammation, atherosclerosis and a decreases in nitric oxide.<sup>84</sup> The vasoconstrictor, endothelin-1 has been shown to upregulate in OSA and in NTG. OSA then has a role in vascular regulation.

OSA has been associated with increasing risk of neurovascular disease (diabetes), including pulmonary, cardiovascular (atherosclerosis, heart disease, peripheral neuropathy), and cerebrovascular disease (stroke, cognitive decline, depression, headache, and nonarteritic ischemic optic neuropathy).<sup>104,105</sup> OSAS also is associated with pulmonary hypertension, myocardial infarction, cardiac arrhythmia, congestive heart failure, stroke, cardiac related mortality, and all may cause mortality.<sup>106</sup>

## Pathology

The pathology of LEC involves a decreased concentration of elastin colocalized with MMP in the tarsal plate (see Fig. 4.17.12).<sup>82,83</sup>

The pathophysiology of FES has been thought to result from a process of ischemia–reperfusion injury from the pressure of the globe onto the eyeball while sleeping. Indeed, the nocturnal eversion of the eyelid with contact of the eyeball and tarsal conjunctiva has been thought to account for the chronic conjunctivitis.<sup>91</sup> Additional hypothesis includes a systemic elastin dysfunction.<sup>84–89</sup>

## TREATMENT

There is a wide variety of eyelid, tear film, conjunctival, corneal, and ocular surface changes that are associated with LES. The eyelid changes include (1) lax eyelids, (2) blepharoptosis, (3) ectropion, (4) lagophthalmos, (5) eyelash ptosis, (4) meibomianitis, and (5) infestation by *Demodex brevis*.<sup>90</sup> Infrared thermography demonstrates increased blood flow to the eyelids and perioral region.<sup>103</sup> Management of eyelid laxity depends on the severity of the disease. For mild disease an eye shield at bedtime might be helpful. Most of these patients, however, use a CPAP machine at night, which precludes the use of a shield. The CPAP device may result in worsening ocular symptoms. For more severe disease, treatment approaches include full thickness upper eyelid wedge resection, and lateral tarsal strip.<sup>107</sup>

The tear film changes include lipid tear deficiency, decreased BUT, and MMP-9 elevation with associated punctate keratopathy (see Table 4.17.2). Most patients also have meibomian gland dysfunction and may benefit from oral omega-3 fatty acids.<sup>108</sup> Short-term topical corticosteroid use and

topical lubricants and gels and ointments at bedtime may be of some benefit.

Conjunctival changes include chronic papillary conjunctivitis associated with nocturnal lid eversion and metalloproteinase elevation. Management of the ocular surface as well as therapeutic bandage with contact lens wear may be tried.

Corneal and ocular surface disease associations include (1) keratoconus, (2) corneal scarring, (3) corneal neovascularization, (4) filamentary keratitis, (5) corneal erosion, (6) microbial keratitis, and (7) corneal thinning/melting.<sup>90</sup> Association with keratoconus is well known and should be suspected in these patients and managed appropriately. Chronic ocular surface disease associated with LES can result in corneal scarring, neovascularization, and microbial keratitis.

Finally, in addition to managing the above eyelid and ocular surface diseases, one of the most important recommendations for ophthalmologists is to identify the patients at risk for OSA and refer them for a sleep study. Evaluation of all patients with complaints of chronic irritation should include a careful evaluation of the eyelid laxity including distraction test of both the upper and lower lids as well as tarsal conjunctival inflammation. Patients with complaints of chronic irritation with a normal Schirmer's score and who are unresponsive to frequent topical preservative-free, teardrops should suggest a diagnosis other than aqueous tear deficiency (caused by *Demodex*, lax eyelids, allergic conjunctivitis). Identification of lax eyelids should prompt an evaluation of sleep apnea and the many associated ocular (and systemic) neurovascular diseases associated with sleep apnea (glaucoma, ischemic optic neuropathy, papilledema, retinal vein occlusion). A careful snoring history needs to be obtained from both the patient and partner as a key element for the diagnosis of sleep apnea and lax eyelid condition (LEC).<sup>106,109</sup> A history of snoring and daytime fatigue as well as lax eyelids should prompt suspicion of sleep apnea.<sup>109,110</sup> STOP-BANG or Berlin Questionnaires validated for diagnosing OSA should also be administered (Video 4.17.1).

## Keratoconus and Other Ectasias

Joel Sugar, Debora E. Garcia-Zaliskak

4.18

**Definition:** Corneal ectasia is a group of disorders affecting the shape of the cornea and include keratoconus, pellucid marginal corneal degeneration, post-refractive surgery corneal steepening, and keratoglobus.

**Key Features**

- Usually bilateral, although often asymmetric.
- Isolated to cornea.
- Noninflammatory.

**Associated Features**

- Obesity.
- Sleep apnea.
- Down syndrome.
- Atopic disease.

**KERATOCONUS**

Keratoconus is a disorder characterized by progressive corneal steepening, most typically inferior to the center of the cornea, with eventual corneal thinning, induced myopia, and both regular and irregular astigmatism.

**Epidemiology and Pathogenesis**

The pathogenesis of keratoconus is not fully understood, although both genetic and environmental processes are likely to be involved. Keratoconus is probably not a single disorder but, rather, a phenotypic expression of several possible causes.

A hallmark of keratoconus is stromal thinning, which may be related to alterations in enzyme levels in the cornea, causing stromal degradation. This is supported by multiple studies suggesting increased levels of degradative lysosomal enzymes and decreased levels of inhibitors of proteolytic enzymes in corneal epithelium.<sup>1,2</sup> These findings are consistent with the observation of increased collagenolytic and gelatinolytic activity in keratoconic cells.<sup>3,4</sup>

Increased apoptosis of stromal keratocytes has been reported in keratoconus, as suggested by confocal microscopy.<sup>5,6</sup> It is postulated that this loss of keratocytes results in a decrease in collagen and extracellular matrix production, leading to reduced stromal mass. Other investigators have suggested that abnormalities in corneal collagen and its cross-linking may be the cause of keratoconus.<sup>7</sup>

Eye rubbing is strongly associated with the development of keratoconus. The mechanism by which eye rubbing contributes to keratoconus is not completely understood, but it may be related to mechanical epithelial trauma, triggering a wound-healing response that leads to keratocyte apoptosis. Other factors, such as slippage of collagen fibrils and a decrease in ground substance viscosity, may play a role.<sup>8</sup> The cytokine interleukin-6 has been suggested as a mediator of eye rubbing and stromal degradation.<sup>9</sup>

The prevalence of keratoconus in the general population varies in different series. A recent study that evaluated 4.4 million patients from a mandatory health insurance database found the estimated prevalence of keratoconus in the general population to be 1 out of 375 persons.<sup>10</sup>

**Ocular Manifestations**

Manifestations of keratoconus include steepening of the cornea, especially inferiorly (Fig. 4.18.1), thinning of the corneal apex, scarring at the level of

**Fig. 4.18.1**  
Characteristic conical steepening of the cornea in keratoconus.

Bowman's layer, and deep stromal stress lines that clear when pressure is applied to the globe. A ring of iron deposition (Fleischer's ring) (Fig. 4.18.2) can accumulate in the epithelium at the base of the cone. Steepening of the cornea leads to clinical signs which include protrusion of the lower eyelid on downgaze (Munson's sign), focusing of a light beam shone from temporally across the cornea in an arrowhead pattern at the nasal limbus (Rizutti's sign), and a dark reflex in the area of the cone on observation of the cornea with the pupil dilated using a direct ophthalmoscope set on plano (Charleaux's sign) (Fig. 4.18.3). In addition, a scissoring reflex can be found on retinoscopy. In some patients who have keratoconus, especially if associated with trisomy 21 (Down syndrome), acute corneal hydrops may occur, in which an abrupt rupture of Descemet's membrane results in acute overhydration of the cornea and accumulation of lakes of fluid within the corneal stroma. Over time, endothelial cells spread over the posterior stromal defect to lay down new Descemet's membrane and recompensate the cornea (Fig. 4.18.4).

**Diagnosis**

Topography and tomography are useful to confirm the diagnosis of keratoconus and, in some cases, even to make the diagnosis of subtle cases without clinical manifestations (see Fig. 4.18.3). Both placido disc and rotating Scheimpflug camera systems for assessing corneal curvature are reliable in distinguishing keratoconic eyes from normal eyes, although there may be differences in posterior elevation measurements between the two systems.<sup>11</sup> The Rabinowitz criteria can be used for the diagnosis of keratoconus, and they include K greater than +47.20 diopters (D), inferior-versus-superior corneal dioptric asymmetry value greater than +1.40 D, KISA% greater than 60%, which is suggestive of the disease, whereas more than 100% strongly suggests keratoconus, and a pachymetry/asymmetry index of less than 105. KISA% index quantifies the topographical features seen in keratoconus. It includes the K-value, the inferior-superior dioptric asymmetry, and the AST index, which quantifies the degree of regular corneal astigmatism.<sup>12</sup>

**Fig. 4.18.2 Severe Apical Thinning in a Cornea With Keratoconus.** A broader slit-beam view of the same cornea (B) reveals extensive stromal apical scarring and linear breaks in Bowman's layer.

**Fig. 4.18.3** Charleaux's sign in keratoconus, delineating the extent of the cone.

Such analyses have been used to demonstrate that keratoconus is almost always a bilateral disease, even when not evident in the fellow eye as seen under at the slit lamp.

The inheritance pattern of keratoconus is incompletely defined. In the past, it was believed that more than 90% of cases were sporadic. With the advent of videokeratography to assess family members, however, pedigrees have been analyzed. These studies show corneal changes consistent with keratoconus in some asymptomatic family members, which suggests an autosomal dominant pattern of inheritance.<sup>13</sup>

### Differential Diagnosis

The differential diagnosis of keratoconus includes pellucid marginal corneal degeneration, post-refractive surgery corneal ectasia, posttraumatic corneal ectasia, protrusion of the cornea after corneal thinning from ulceration, and keratoglobus.

### Systemic Associations

A number of systemic and ocular disorders have been described in association with keratoconus. Conditions found to have increased odds of keratoconus include sleep apnea, asthma, and Down syndrome. Interestingly, patients with diabetes mellitus and collagen vascular disease

**Fig. 4.18.4 Massive Hydrops in Keratoconus.** Note the large tear in Descemet's membrane.

have been found to have lower odds of keratoconus, and no association has been found between keratoconus and allergic rhinitis, mitral valve disorder, aortic aneurysm, or depression.<sup>14</sup> Other systemic associations include Ehlers–Danlos, Marfan's, Cruzon's, and Apert's syndromes. Ocular-associated disorders include Leber's congenital amaurosis, retinitis pigmentosa, and retinopathy of prematurity. Fuchs' dystrophy and posterior polymorphous dystrophy have been reported as well.

### Pathology

Histopathology shows irregular epithelium and breaks in Bowman's layer with fibrosis filling in the breaks and extending beneath the epithelium (Fig. 4.18.5), and central corneal thinning. With hydrops, breaks at the level of Descemet's membrane are seen with inward curling of the membrane, which is otherwise normal. Electron microscopy shows decreased thickness of the cornea with fewer lamellae. The collagen fibrils in the lamellae are thinned mildly, and the space between fibrils is decreased.<sup>15,16</sup>

### Treatment

Treatment consists of spectacles for myopic astigmatism and then rigid contact lenses or scleral lenses once spectacle-corrected visual acuity

**Fig. 4.18.5 Keratoconus.** Breaks in Bowman's layer, with fibrosis that extends beneath the epithelium, can be seen. The stroma shows scarring.

(SCVA) becomes inadequate. When contact lenses fail, surgical treatment is indicated. In one series, the reasons for penetrating keratoplasty were contact lens intolerance (83%), frequent contact lens displacement (8.5%), and unsatisfactory visual acuity despite good fit of contact lenses (8.5%).<sup>17</sup>

Standard surgical treatment consists of deep anterior lamellar keratoplasty (DALK) or penetrating keratoplasty (PKP). Keratoconus accounted for 14.8% of all penetrating keratoplasty and 38.3% of all DALK carried out in the United States in 2015.<sup>18</sup> At the time of keratoplasty, decreasing the donor/recipient size disparity reduces postkeratoplasty myopia.<sup>19</sup> Primary advantages of DALK over PKP include increased structural integrity and reduced risk of graft rejection. Some surgical techniques, such as the big-bubble technique, have reduced surgical operating time, though it remains challenging to perform, especially for inexperienced surgeons.<sup>20</sup> Bowman's layer graft is another surgical technique in the treatment of keratoconus. It was shown to be beneficial in a small series, where reduction and stabilization of corneal ectasia were achieved in eyes with progressive, advanced keratoconus.<sup>21</sup>

Intracorneal ring segments, first described for keratoconus in 2000,<sup>22</sup> have been shown in several studies to be successful in reducing myopia and astigmatism and improving SCVA.<sup>23</sup> The ring segments can be inserted into the stroma either via mechanical dissection or femtosecond laser assistance. Currently Intacs (Addition Technology, Sunnyvale, CA) is the only intrastromal corneal ring segment approved in the United States.

Another less invasive technique that was approved by the Food and Drug Administration (FDA) in the United States in August 2016 is combined riboflavin–ultraviolet A rays (UVA) corneal cross-linking. This procedure, first described in 1998,<sup>24</sup> consists of photopolymerization of corneal stroma by combining riboflavin (photosensitizing substance) with UVA. This process increases corneal rigidity and thus reduces the likelihood of further ectasia. Cross-linking is indicated in patients with documented progressive corneal ectasia. Contraindications include corneal thickness less than 400 microns (although use of hypotonic solutions may allow swelling to greater than this level prior to treatment), prior herpetic infection, concurrent infection, severe corneal scarring, history of poor epithelial wound healing, severe ocular surface disease, and autoimmune disorders.<sup>25</sup> Various protocols with different treatment and epithelium handling are under ongoing evaluation. Currently, the only FDA-approved protocol in the United States is the “epithelium off” protocol, where the cornea is treated after epithelial removal, but “transepithelial” corneal cross-linking continues to be studied and refined.<sup>26–28</sup>

## Course and Outcome

The natural course of untreated keratoconus can be unpredictable, although progressive myopia, irregular astigmatism, and corneal scarring are typical. It is widely estimated that 10%–20% of patients with keratoconus undergo keratoplasty, although a recent report found as much as a 25% reduction in the performance of keratoplasty since corneal cross-linking began to be used.<sup>29</sup> Keratoplasty outcomes in terms of graft clarity and improved vision are excellent, although residual astigmatism and myopia remain problematic. Recurrence of keratoconus after keratoplasty may rarely occur, although thinning and ectasia at the inferior host-graft junction is not uncommon 15 or more years after keratoplasty. Some authors

**Fig. 4.18.6 Pellucid Marginal Corneal Degeneration.** The point of greatest protrusion is just above the area of maximal thinning (located inferiorly).

have postulated that recurrence could be related to incomplete excision of the cone at the time of surgery, unrecognized keratoconus in the corneal donor, or host cellular activity that causes changes in the donor corneal material.<sup>30</sup>

In one study on the long-term outcomes of intracorneal ring segments, with 17 eyes and 5-year follow-up, Intacs placement reduced mean spherical equivalent refractive error from  $-5.54 \pm 5.02$  D to  $-3.02 \pm 2.65$  D ( $P = .01$ ), reduced mean keratometry from  $49.59 \pm 5.10$  D to  $48.02 \pm 4.99$  D ( $P = .009$ ), and improved uncorrected visual acuity in 77% of patients.<sup>31</sup> Complications of Intacs include infection, corneal melt, and ring extrusion. One study showed significant postoperative problems in 30% of Intacs with thinning and ring exposure.<sup>32</sup>

Results of long-term follow-up of corneal cross-linking are promising. Data from the Siena Eye Cross Study in Italy revealed a mean hyperopic shift in spherical equivalent of +2.15 D and a mean reduction in keratometry of +2.26 D on 4-year follow-up of 44 patients.<sup>33</sup> Complications include temporary stromal edema, temporary or permanent corneal haze, corneal scarring, sterile infiltrates, infectious keratitis, and diffuse lamellar keratitis.<sup>34–38</sup>

Both intracorneal ring segments and corneal cross-linking are most likely to be beneficial in patients with mild to moderate keratoconus without corneal scarring; in these patients, stabilization of keratoconus may obviate or delay the need for keratoplasty. More advanced cases typically need keratoplasty for optimal visual outcome.

## PELLUCID CORNEAL DEGENERATION

Pellucid marginal corneal degeneration appears to be a variant of keratoconus, with some different clinical features. Corneal thinning and protrusion are seen in the inferior peripheral cornea; the thinning begins 1–2 mm inside the inferior limbus in a horizontal oval band approximately 2 mm in radial extent and 6–8 mm in horizontal extent (Fig. 4.18.6). The involved area is clear, and usually no iron line occurs central to it. Hydrops may occur. The central cornea is regular, but usually with marked against-the-rule astigmatism. Some patients who have pellucid may have more typical central corneal changes of keratoconus, as may family members, although the inheritance of pellucid is not clear. Pathology appears to be the same as in keratoconus. Treatment, as for keratoconus, consists of spectacles or contact lenses. When these modalities are insufficient, results are best found with large, eccentric keratoplasty. Outcomes of keratoplasty in pellucid marginal degeneration are poorer than in keratoconus because of the more peripheral location of corneal thinning.

## KERATOGLOBUS

### Epidemiology and Pathogenesis

At least two forms of keratoglobus appear to exist: (1) a congenital or juvenile form and (2) an acquired adult form. The acquired form may be an

end-stage form of keratoconus—patients have been described with initial keratoconus followed by later keratoglobus—or acquired keratoglobus may be seen with no known prior keratoconus. The congenital form appears to be part of at least two different autosomal recessive syndromes. One is Ehlers–Danlos syndrome type VI. Another clinically similar syndrome, but with normal lysyl hydroxylase activity, is brittle corneal syndrome with associated blue sclera and red hair, which mimics Ehlers–Danlos syndrome type VI.<sup>39</sup>

## Ocular Manifestations

Keratoglobus is a disorder characterized by the presence of limbus-to-limbus corneal thinning with globular corneal protrusion. The thinning is usually greatest in the corneal periphery or midperiphery. Hydrops may occur, and perforations may result from relatively minor trauma. In Ehlers–Danlos syndrome type VI, patients have diffuse corneal thinning with corneal rupture spontaneously or after minor trauma, and corneal hydrops is common. Blue sclerae are present. These patients may have systemic connective tissue abnormalities as well, with hyperextensible joints, bone anomalies, and hearing loss.<sup>39</sup> A defect in lysyl hydroxylase activity is present.

## Pathology

Pathology of acquired keratoglobus is similar to that of keratoconus, whereas congenital keratoglobus shows an absence of Bowman's membrane, stromal disorganization, and thickening of Descemet's membrane with breaks.<sup>40</sup>

## Treatment

Treatment includes protection from trauma. Outcomes of penetrating keratoplasty are typically poor because of severe host peripheral thinning. Lamellar epikeratoplasty has been used successfully to reinforce thin corneas and, in some cases, to improve vision.<sup>41</sup> For acquired keratoglobus, large penetrating keratoplasty may be successful.

## POSTERIOR KERATOCONUS

*Posterior keratoconus* refers to a congenital corneal anomaly in which the posterior corneal surface protrudes into the stroma, which usually occurs in a localized area, but may be more diffuse. This disorder usually is sporadic, unilateral, and nonprogressive. Bilateral and familial cases do occur but are less frequent. The anterior corneal contour is often affected minimally, although anterior protrusion and even a surrounding iron line have been described. Frequently, scarring occurs in the stroma anterior to the Descemet's bulge. On pathological examination, scarring at the level of Bowman's membrane is seen and thinning of Descemet's membrane with excrescences has been reported variably.<sup>42,43</sup> Descemet's membrane changes and congenital nature of this disorder suggest that it is a variant

of corneal mesenchymal dysgenesis. Treatment usually is not necessary, although occasionally keratoplasty is indicated.

## POST-REFRACTIVE SURGERY CORNEAL ECTASIA

Corneal ectasia is an uncommon yet serious complication that can occur after refractive surgery. Its prevalence has been reported to be 0.04%–0.6%, although some believe this is an underestimation. Ectasia is thought to be a consequence of disrupting the biomechanical integrity of the cornea below a certain threshold. The FDA's current guidelines prohibit leaving less than 250  $\mu\text{m}$  of untouched tissue, but most refractive surgeons prefer to leave 300  $\mu\text{m}$  or more.<sup>44</sup> Risk factors for ectasia include an abnormal preoperative corneal topography, >40% of tissue altered, a low preoperative corneal thickness, high myopia, and younger age.<sup>44,45</sup>

Corneal cross-linking has currently emerged as a proposed treatment to not only treat but also, ideally, prevent corneal ectasia that occurs after refractive surgery. A recent study from Japan found no case of post-LASIK ectasia in 673 eyes, with follow-up ranging from 3 months up 3.5 years. Given the prevalence of ectasia, as stated above, this may or may not be clinically significant, but more studies should be performed for further evaluation.<sup>46</sup>

## Anterior Corneal Dystrophies

Michael H. Goldstein, Joel Sugar, Bryan Edgington

4.19

**Definition:** Bilateral disorders, most of which are inherited, in which an abnormal substance accumulates primarily in the corneal epithelium.

**Key Features**

- Typically bilateral.
- Progressive.
- Involvement is anterior to corneal stroma.

**Associated Features**

- Many are associated with recurrent erosion syndrome.
- Not associated with systemic disease, with rare exceptions.

**INTRODUCTION**

In general, most corneal dystrophies are autosomal dominant, bilateral disorders that primarily affect one or more layers of an otherwise normal cornea, progress slowly after their appearance in the first or second decade, and are not associated with any systemic disease. Historically, corneal dystrophies were categorized by the involved corneal layer. The distinctive clinical appearance of most corneal dystrophies allows accurate diagnosis based on clinical grounds. Transmission electron microscopy is the most accurate method for histopathological diagnosis.<sup>1</sup> Genetic studies on corneal dystrophies, however, also provide insight at a basic molecular level and are assisting in refining the classification systems. Several corneal dystrophies are closely related at the molecular level with different phenotypes resulting from mutations within the same gene. For example, the *BIGH3* gene on chromosome 5q31 is associated with granular corneal dystrophy (types I, II, and III), lattice corneal dystrophy (types I, IIIA, IIIA-like, and IV), and corneal dystrophy of Bowman's layer (types I and II).<sup>2</sup>

The anterior corneal dystrophies involve Bowman's layer and involve the epithelium as well. Some also may involve the anterior stroma. This categorization, however, is arbitrary because many of the stromal dystrophies also involve Bowman's layer and the epithelium. The genetic understanding of these disorders makes this classification even less appropriate, and many of these conditions will ultimately be better classified and named by their specific biochemical defects (Table 4.20.1).<sup>3</sup>

**ANTERIOR BASEMENT MEMBRANE DYSTROPHY****Introduction**

Anterior basement membrane dystrophy (ABMD), also termed *epithelial basement membrane dystrophy* (EBMD), *map-dot-fingerprint corneal dystrophy*, and *Cogan's microcystic dystrophy*, is the most common anterior corneal dystrophy.<sup>1</sup>

**Epidemiology and Pathogenesis**

ABMD has been reported to occur in approximately 3%–6% of the general population but is much more common over age 40 years.<sup>4,5</sup> Familial patterns have been described for ABMD,<sup>4</sup> but many patients with the disorder will not have any known family history, which has caused some debate as to whether ABMD is actually a corneal dystrophy or a degenerative change.<sup>3</sup> Point mutations in the *TGFBI/BIGH3* gene have been reported in two families showing autosomal dominant inheritance.<sup>6</sup>

**Ocular Manifestations**

The most common clinical manifestations of ABMD are recurrent erosion syndrome (RES) and blurry or distorted vision. Most patients with RES describe mild pain on awakening, subsiding within minutes to hours, but larger erosions can cause severe pain, which may take hours to days to resolve. Patients also note blurred vision or occasionally monocular diplopia or image ghosting. Although ABMD is often thought to be the most common cause for RES, other conditions (including trauma), can cause RES.<sup>7–9</sup> In some cases, both entities are present, and the diagnosis of ABMD is made by carefully examining the unaffected eye after trauma. Patients with ABMD and a history of a traumatic abrasion are even more likely to develop RES. The clinical symptoms of ABMD overlap considerably with recurrent erosions secondary to trauma. In both conditions, recurrent erosions are felt to be secondary to friability of the superficial epithelium caused by poor adhesion of epithelial cells to each other and to the underlying basement membrane.<sup>10,11</sup>

In patients with blurred or distorted vision, which is thought to be related to central ABMD changes, corneal topography can be very helpful in identifying irregular astigmatism as the source of the visual problem. In addition, a trial with a soft bandage contact lens can be a helpful diagnostic or therapeutic tool.

ABMD is characterized by several changes apparent in the anterior cornea on slit-lamp examination. They often are seen best with a dilated pupil and retroillumination. Cases may be subtle and can be detected by looking for negative staining using cobalt blue filter after the application of fluorescein (Fig. 4.19.1). Corneal findings seen with ABMD include intra-epithelial microcysts (dots) (Fig. 4.19.2), map-like grayish patches, and fingerprint parallel lines (Fig. 4.19.3).<sup>12–14</sup> The condition is referred to as Cogan's microcystic dystrophy when only microcysts are present. Confocal microscopy is helpful in corneas with a history of erosions that appear to be normal on clinical examination. With confocal microscopy, corneas with recurrent erosions or ABMD showed deposits in basal epithelial cells, subbasal microfolds and streaks, damaged subbasal nerves, or altered morphology of the anterior stroma.<sup>15,16</sup>

**Fig. 4.19.3** Prominent epithelial map lines in a patient with epithelial basement membrane dystrophy. (Courtesy Anthony J. Aldave, MD.)

## Pathology

The clinical appearance of ABMD corresponds well with the pathology. Specimens from affected patients show protrusions of sheets (maps) or rows of thickened basement membrane (fingerprints) into the superficial epithelium as well as mounds of thickened basement membrane beneath the epithelium. Microcysts of degenerated cellular material accumulate within the epithelium (dots). A bilaminar subepithelial layer of fibrogranular material often occurs.<sup>1,10,11</sup>

## Treatment

The majority of patients with recurrent corneal erosions will respond to conventional forms of therapy, such as topical lubricants, patching, debridement, or bandage soft contact lenses.<sup>17</sup> Topical hyperosmotic solutions are well tolerated and appear to be effective in treating recurrent corneal erosion in some cases.<sup>18</sup> Therapy with a combination of medications that inhibit metalloproteinase-9 (topical corticosteroid and oral doxycycline) may produce rapid resolution and help prevent further recurrence in cases unresponsive to conventional therapies.<sup>19</sup>

In some cases, surgical intervention will be required. Anterior stromal micropuncture, superficial keratectomy, excimer laser ablation (phototherapeutic keratectomy [PTK]), and diamond burr (DB) superficial keratectomy have all been used.<sup>8</sup> Anterior stromal puncture was the first to be described, and presumably stimulates more secure epithelial adhesion

to the underlying stroma.<sup>17</sup> The use of 23- or 25-gauge needles instead of 30-gauge needles may decrease the risk of corneal perforation.<sup>20</sup> Micropuncture should be used with caution for erosions in the visual axis because central corneal scarring can lead to decreased vision.

PTK is a safe and effective procedure for recurrent corneal erosions (trauma and ABMD) refractory to conventional treatment as well as to treat visually significant ABMD.<sup>21–25</sup> In the great majority of patients, visual fluctuation and monocular diplopia or “ghost images” resolved.<sup>21–24,26</sup> A hyperopic shift can be an adverse side effect in some individual cases.<sup>19,24</sup> It is possible to combine PTK with PRK to manage the hyperopic shift in select patients.<sup>27–29</sup> ABMD has been reported as a risk for increasing complication rates after laser-assisted in situ keratomileusis (LASIK) including epithelial defects and epithelial ingrowth, so these patients may be better candidates for photorefractive keratectomy (PRK).<sup>30</sup>

DB superficial keratectomy appears to be an effective and safe method of treating recurrent erosions (both posttraumatic and ABMD). Little refractive shift occurs with this method.<sup>31,32</sup> As an alternative to DB, an Amoils epithelial scrubber may be used to debride the epithelium and buff Bowman's layer.<sup>33</sup> The DB procedure is simple, office-based, and inexpensive, so it may be the preferred technique in some settings.<sup>34</sup>

## MEESMANN'S EPITHELIAL DYSTROPHY

Meesmann's epithelial dystrophy is a rare, bilateral condition confined to the corneal epithelium. It is an autosomal dominant disorder that leads to fragility of the anterior corneal epithelium. It has been linked to mutations in locus 12q13 (KRT3) and 17q12 (KRT12) that are specifically expressed in the epithelium.<sup>35–38</sup>

Symmetrical intraepithelial microcysts appear in the first few years of life and are visible only at the slit lamp. They are concentrated within the visual axis and midperiphery. They are seen best with indirect illumination or retroillumination. Typically, patients are either asymptomatic or report mild symptoms, including recurrent erosions or minimal loss of visual acuity. These symptoms usually can be treated with topical lubricants only. Surgical intervention is rarely needed.

Histological examination shows two characteristic findings in the corneal epithelium: (1) intracellular “peculiar substance” and (2) intraepithelial microcysts containing cellular debris.<sup>39–41</sup> The epithelial cells are rich in glycogen and many contain the fibrogranular “peculiar substance,” possibly derived from tonofilaments.<sup>31,32</sup> Moreover, a nonspecific thickening of the epithelial basement membrane occurs without any apparent modification of Bowman's layer or superficial stroma.<sup>39–41</sup>

## REIS-BÜCKLER DYSTROPHY

### Introduction

“True” Reis-Bückler dystrophy, also known as *corneal dystrophy of Bowman's layer type I* (CDB I) or granular dystrophy type III, is discussed here.

### Epidemiology and Pathogenesis

Reis-Bückler dystrophy has an autosomal dominant inheritance and has been linked to a specific defect in the keratoprotein gene on chromosome 5q31. An arginine replaced by a glycine at codon 555 has been found in families with this disorder, although other defects have been found in other families.<sup>42,43</sup> No systemic associations are known. The diagnosis is made on the basis of clinical appearance, although differentiation from honeycomb dystrophy often is difficult.

### Ocular Manifestations

Reis-Bückler dystrophy is characterized by recurrent, painful, corneal epithelial erosions that often begin in the first 1–2 years of life. Minimal corneal changes are seen at first, but then ring and map-like opacities appear at the level of Bowman's membrane; these become denser and more irregular over time (Fig. 4.19.4). By the second or third decade of life, the painful erosions diminish as corneal sensitivity decreases, but the increasing fibrosis results in visual difficulty.

### Pathology

Pathology shows eosinophilic and fibrotic material beneath the corneal epithelium and within the anterior stroma, with destruction of Bowman's membrane. The material is somewhat granular in appearance. Electron

**Fig. 4.19.4 Reis–Bückler Corneal Dystrophy.** Note the irregular opacities at the level of Bowman's layer.

microscopy shows rod-shaped bodies that replace Bowman's layer and lie between epithelial cells. These pathological findings are the same as those seen in superficial granular dystrophy (granular dystrophy type III).

### Treatment

Treatment of Reis–Bückler dystrophy is symptomatic for the recurrent erosions. Superficial keratectomy, either by mechanical stripping or by excimer laser ablation, is the appropriate treatment for the visual disturbance. Recurrence may be relatively rapid and keratoplasty may become necessary after multiple treatments.

### THIEL–BEHNKE DYSTROPHY

Also known as *honeycomb dystrophy*, *Waardenburg and Jonkers dystrophy*, or *corneal dystrophy of Bowman's membrane II* (CDB II), Thiel–Behnke dystrophy often is confused in the literature with Reis–Bückler dystrophy. Patients have recurrent erosions, although less severe than those associated with Reis–Bückler dystrophy. A reticular array of anterior stromal opacities develops and elevates the corneal epithelium in a “saw-tooth”

pattern. The disorder is inherited as an autosomal dominant disorder. A defect has been found in the keratoepithelin gene.<sup>44</sup>

In one family, a defect was found on chromosome 10q24. No known associated systemic abnormality exists. Histopathology shows wavy, sub-epithelial fibrosis with disruption of Bowman's layer and epithelial basement membrane. Electron microscopy reveals that curly collagen filaments replace Bowman's layer.<sup>45</sup> Treatment is the same as that for Reis–Bückler dystrophy, namely, superficial keratectomy or excimer ablation. Keratoplasty may become necessary after multiple recurrences.

# Stromal Corneal Dystrophies

Joel Sugar, Praneetha Thulasi

4.20

**Definition:** An inherited, bilateral disorder in which an abnormal substance accumulates in the cornea.

**Key Features**

- Characteristically bilateral.
- Progressive.
- Isolated to the cornea.

**Associated Features**

- Usually autosomal dominant.
- Not associated with systemic disease, with rare exceptions.

INTRODUCTION

Corneal dystrophy is classically bilateral, progressive, and isolated to the cornea. The disorder is generally inherited, usually in a dominant fashion, and often appears clinically to involve only one layer of the cornea. With the progressive identification of genes involved in these entities, a better pathophysiological understanding and ultimately better treatment will be developed. Epithelial and endothelial dystrophies are discussed in their respective chapters.

The stromal dystrophies are classified as such because they appear to accumulate material predominantly in the stroma. As was noted in Chapter 4.19 this categorization is, however, arbitrary because many of the stromal dystrophies also involve Bowman’s layer and the epithelium. The genetic understanding of these disorders makes this classification even less appropriate. Many of these conditions ultimately will be classified and named by their specific biochemical defects (Table 4.20.1). The classification of corneal dystrophies has recently been reviewed in 2015 and standardized by an international committee and published as “The International Classification of Corneal Dystrophies (IC3D).”<sup>1</sup>

GELATINOUS DROP-LIKE DYSTROPHY

Gelatinous drop-like dystrophy was previously categorized as stromal but is now considered an epithelial/subepithelial dystrophy, as described in the most recent IC3D classification.

LATTICE DYSTROPHY TYPE I

Genetics

This disorder is autosomal dominant, with mutation in the transforming growth factor- $\beta$ -induced (*TGFBI*) gene, resulting in abnormal

keratoepithelin production at locus 5q31. The most common mutation is at codon 124, where arginine is replaced by cysteine.

Ocular Manifestations

Rod-like glassy opacities appear in the anterior stroma in the first or second decade and become denser over time, resulting in linear, often branching opacities (Figs. 4.20.1 and 4.20.2). These opacities are most dense anteriorly and centrally, with a clear zone in the periphery. The lines are relatively fine, as opposed to the more ropy opacities seen in lattice dystrophy type III. Although this disorder is bilateral, it can be asymmetrical.

Clinical Presentation

Patients often present in their first and second decades with pain and decreased vision. Recurrent erosions are common and, over time, can lead to anterior stromal haze that can limit vision. Patients often need corneal transplantation by their fourth decade.

**Fig. 4.20.1 Lattice Dystrophy Type I.** This patient has very fine, rod-like opacities in the anterior stroma.

**Fig. 4.20.2 Lattice Dystrophy Type I.** Denser, ropier opacities than those shown in Fig. 4.20.1.

**TABLE 4.20.1** Corneal Dystrophies Due to Keratoepithelin Gene Defects

Dystrophy	Defect
Reis-Bückler’s	Arg555Gly, Arg124Leu, Arg555Gln
Thiel-Behnke	Arg124Leu (other families chromosome 10)
Lattice I	Arg124Lys
Lattice IIIA	Arg124Thr, Pro501Thr
Lattice IV	Leu527Arg
Granular I	Arg555Trp, Arg124Ser
Granular II (Avellino)	Arg124His

**Fig. 4.20.3 Lattice Dystrophy Type I.** Histopathology using Congo red stain shows the amyloid accumulations throughout the stroma (arrows).

## Pathology

Histopathologically, dense deposits are seen in the stroma. These stain with Congo red, periodic acid–Schiff (PAS), and Masson's trichrome (Fig. 4.20.3). Dichroism and birefringence are seen with polarized light and fluorescence is seen with thioflavin-T. All of these findings are characteristic for amyloid, a  $\beta$ -pleated protein structure. The amyloid appears to be distinct from that seen in lattice dystrophy type II.<sup>2</sup> Descemet's membrane and the endothelium are normal. Electron microscopy shows extracellular masses of fine, electron-dense randomly aligned fibrils characteristic of amyloid protein.<sup>3</sup>

## Treatment

Initial treatment consists of soft contact lenses for corneal epithelial erosions. Phototherapeutic keratectomy may be a good option to treat anterior visually significant deposits, although epithelial healing may be delayed, and recurrences may occur.<sup>4</sup> When visual acuity decreases significantly, deep anterior lamellar keratoplasty (DALK) is the procedure of choice because it has a benefit over penetrating keratoplasty (PKP) in minimizing the risk of rejection.<sup>5</sup> Epithelial cells are thought to be the source of these deposits, and although PKP has not shown statistically significant results, presence of transplanted limbal stem cells may have fewer recurrences.<sup>6</sup> Recently, investigators have been studying the efficacy of fibronectin drops after corneal epithelium debridement in improving visual acuity in this condition.<sup>7</sup>

## SYSTEMIC AMYLOIDOSIS WITH CORNEAL LATTICE

### Genetics

Locus 9q34 mutation in gelsolin protein is involved in actin modulation.

### Ocular Manifestations

Often classified as lattice dystrophy type II, this is part of the systemic disorder familial amyloid polyneuropathy type IV (Finnish type), also known as Meretoja's syndrome. In this disorder, fine lattice lines extend to the limbus and are not related to corneal nerves, although the sub-basal nerve density is reduced.<sup>8</sup> Patients may have increased risk of glaucoma and also can present with facial weakness with lid lag.

Systemic associations include multiple cranial neuropathies and systemic amyloid deposition.

### Patient Presentation

Patients often present with this condition during routine examinations. Visual disturbance is less compared with that in lattice dystrophy type I, and recurrent erosions are less frequent. Patients also can present with lid lag and corneal exposure.

**Fig. 4.20.4 Granular Dystrophy.** Note the more crumb-like opacities in this patient who has sufficient clear cornea to have normal acuity.

## Pathology

The pathology is similar to that of lattice dystrophy type I.

## Treatment

Treatment, if necessary, is the same as for lattice dystrophy type I, although additional consideration must be given to the risk of corneal exposure from facial neuropathy. Animal studies on gene silencing therapy hold promise.<sup>9</sup>

## Other Lattice Dystrophies

Multiple subtypes of lattice dystrophy have been described based on genotypical and phenotypical variations, especially as the genetics of those with atypical features are further explored. Lattice dystrophy types III, I/III, and IV and the polymorphic variant have delayed onset at age greater than 40 years and have thicker, ropy lattice lines.<sup>10,11</sup> Type IIIA has identical changes but has more recurrent erosions.<sup>12</sup> Many of these variants are geographically restricted.

## GRANULAR CORNEAL DYSTROPHY TYPE I

### Genetics

This disorder is autosomal dominant, with mutation in the *TGFBI* gene at locus 5q31.

### Ocular Manifestation

Previously called *Groenouw's dystrophy type I*, granular corneal dystrophy is characterized by the presence of discrete opacities in the corneal stroma that do not extend to the limbus, and the intervening stroma is clear. The opacities have irregular crumb-like or flake-like shapes and are whitish or slightly glassy in appearance (Fig. 4.20.4). The pattern within a given family appears to be consistent. No systemic associations are known.

### Patient Presentation

Many patients have no symptoms, whereas some patients develop recurrent erosions. In the fifth decade or later, some patients develop visual difficulties as the opacities become prominent in the superficial stroma. Anterior stromal opacities tend to be much more visually significant than posterior stromal opacities.

## Pathology

Histopathological findings show red staining (Fig. 4.20.5) with Masson's trichrome stain without Congo red staining. Electron microscopy shows electron-dense, rod-like deposits and microfibrils, which are present in keratocytes as well as epithelial cells.<sup>13</sup> The material is thought to be phospholipid.

**Fig. 4.20.5 Granular Corneal Dystrophy.** Masson's trichrome staining shows accumulation of hyaline material in the corneal stroma and beneath the epithelium.

**Fig. 4.20.6 Macular Corneal Dystrophy.** Note the stromal haze between the denser macular opacities in this 40-year-old woman.

## Treatment

Because the superficial deposits are often the most visually significant, vision often improves with excimer ablation and does not impair future keratoplasty.<sup>14,15</sup> Patients who require keratoplasty do well, and DALK is the procedure of choice.<sup>16</sup> Granules do recur superficially in the graft, at times in a swirling pattern that suggests the epithelium is the source of the deposits.<sup>16</sup> There are a few case reports of concurrent limbal stem cell transplantations with improved long-term outcomes.<sup>17</sup>

## GRANULAR CORNEAL DYSTROPHY TYPE 2

A dystrophy that combines features of both granular and lattice dystrophies has been described, with the majority of the original patients coming from the Avellino region of Italy. This is also referred to as *Avellino granular dystrophy*.

## Genetics

This disorder is autosomal dominant, with mutation in the *TGFBI* gene at locus 5q31.

## Ocular Manifestations

Patients have granular deposits in the anterior stroma along with lattice-like lines deeper within the stroma. These lines rarely cross and are whiter than lattice corneal dystrophy. A gray subepithelial haze may develop centrally after repeat corneal erosions and can affect visual acuity.

## Patient Presentation

Similar to granular corneal dystrophy type I, patients often present with decreased vision over time and may have epithelial erosions. Homozygotes have worse symptoms compared with heterozygotes.<sup>18,19</sup>

## Pathology

Histopathology shows superficial, discrete, red granular deposits with Masson's trichrome stain, as well as mid-to-deep stromal fusiform deposits with the typical Congo red and other stains characteristic of lattice dystrophy type I.<sup>20</sup>

## Treatment

Treatment is the same as for granular and lattice dystrophies. These individuals, even heterozygotes, are at high risk of aggressive recurrence of deposits predominantly in the interface if they undergo laser in situ keratomileusis (LASIK).<sup>21-23</sup> Although surface ablation by itself can lead to mild exacerbation, it may improve vision and delay corneal transplantation, with heterozygotes doing better than homozygotes.<sup>24</sup>

## MACULAR CORNEAL DYSTROPHY

In macular corneal dystrophy, three types have been defined on the basis of immunoreactivity to specific markers of antigenic keratan sulfates (AgKS). In type I, there is no AgKS reactivity in the cornea or in the serum. In type IA, the keratocytes manifest AgKS reactivity, but neither the serum nor the extracellular material in the cornea does.<sup>25</sup> In type II, all the abnormal deposits in the cornea as well as the serum have positive AgKS reactivity. Clinically and histopathologically, types I and II are indistinguishable.<sup>26</sup>

## Genetics

This disorder is autosomal recessive, with mutations in the *CHST6* gene at locus 16q22, leading to abnormal keratan sulfate.<sup>27</sup>

## Ocular Manifestations

Faint anterior stromal white opacities are seen early in life, often in the first decade. The opacities progress over time and a grainy, ground-glass haze becomes evident between the opacities and then throughout the stroma from limbus to limbus, down to Descemet's membrane. Over time, the cornea thins,<sup>28</sup> and the endothelium may develop guttae, although endothelial decompensation is rare (Fig. 4.20.6).

Although abnormalities in keratan sulfate in the blood and in cartilage have been reported, no systemic clinical abnormalities have been found in patients who have macular corneal dystrophy.

## Patient Presentation

Patients often present with decreased vision and photophobia in their second and third decades. They also may have recurrent erosions and decreased corneal sensitivity.

## PATHOLOGY

Pathology shows glycosaminoglycan (GAG) accumulation within and outside stromal keratocytes, beneath the corneal epithelium, and within corneal endothelial cells. This is evident with Alcian blue, colloidal iron (Fig. 4.20.7), and PAS staining. Electron microscopy shows intracytoplasmic vacuoles that contain GAGs, and the extracellular matrix contains fibrillogranular GAGs.<sup>29</sup>

## Treatment

Treatment consists of corneal transplantation and has good outcomes. In those without apparent endothelial involvement, DALK has shown comparable results to PKP in multiple studies at up to 5 years of follow-up.<sup>30-32</sup> Although PKP has a higher risk of rejection, DALK has a higher risk of endothelial failure. Higher rates of intraoperative perforations and need for conversion to PKP have been reported. Phototherapeutic keratectomy can improve vision for a short period but there is a high risk of recurrence.<sup>33</sup>

**Fig. 4.20.7 Macular Corneal Dystrophy.** Colloidal iron shows accumulation of glycosaminoglycan at all levels of the cornea.

**Fig. 4.20.8 Schnyder's Crystalline Dystrophy.** This patient has a paracentral ring of crystals. (Courtesy Frederick Brightbill, MD.)

Determining absence of endothelial involvement at the time of surgery remains a challenge. Recurrence in grafts is infrequent.

## SCHNYDER'S CORNEAL DYSTROPHY

### Genetics

This disorder is autosomal dominant, with mutation in the UBIA phenyltransferase domain containing 1 (*UBIAD1*) gene at locus 1p36 and is involved in the synthesis of vitamin K<sub>2</sub>.

### Ocular Manifestations

Schnyder's corneal dystrophy is an autosomal dominant disorder with variable phenotypical expression. Younger patients present with central corneal opacity with or without central subepithelial corneal crystals (Fig. 4.20.8). With advancing age, arcus lipoides and more diffuse stromal haze may emerge. In up to 50% of patients, however, even in those from the same family, such crystals may not be evident. Weiss called this *Schnyder's crystalline dystrophy sine crystals*.<sup>34</sup>

Systemic hypercholesterolemia is frequent both in affected and unaffected family members.<sup>35</sup> Genu valgum (knock-knees) is rarely associated.<sup>36</sup>

**Fig. 4.20.9 Findings Typical of Central Cloudy Dystrophy (Posterior Crocodile Shagreen).** Such patients are almost always asymptomatic.

## Patient Presentations

Patients complain of severe photophobia. They often can have decreased corneal sensation and may retain much better scotopic vision than photopic vision.

## Pathology

Histopathology shows oil red O–positive material throughout the stroma, which is more prominent peripherally, in Bowman's membrane, and just anterior to Descemet's membrane. If a surgeon suspects Schnyder's corneal dystrophy, it is advisable to send fresh tissue that has not been preserved. Electron microscopy shows membrane-bound intracellular and extracellular vacuoles that contain electron-dense materials throughout the stroma and cholesterol clefts that may be seen in the anterior stroma.<sup>37</sup> The accumulated material appears to be phospholipid with esterified and unesterified cholesterol.

## Treatment

Treatment consists of DALK when the acuity declines sufficiently.<sup>38</sup> Phototherapeutic keratectomy may be beneficial in some patients.<sup>39</sup> Corneal erosions may result in better vision after their resolution because of decreased number of superficial crystals.<sup>40</sup>

## CENTRAL CLOUDY DYSTROPHY

### Genetics

This disorder is autosomal dominant, with no genetic abnormality.

### Ocular Manifestations

Central cloudy dystrophy, also known as *central cloudy dystrophy of François*, has the same clinical appearance as Vogt's posterior crocodile shagreen, with the exception being that central cloudy dystrophy appears to be dominantly inherited, whereas posterior crocodile shagreen appears to be sporadic. These disorders have central corneal haze in a mosaic pattern like that on crocodile skin and involves the posterior stroma (Fig. 4.20.9).

## Patient Presentations

Patients often are asymptomatic.

## Pathology

Histopathology shows a "saw-tooth" disarray of the corneal stromal lamellae.<sup>41</sup> Electron microscopy shows extracellular vacuoles, some containing fibrillogranular material and electron-dense deposits.<sup>42</sup>

## Treatment

No treatment is necessary.

## FLECK DYSTROPHY

Fleck dystrophy is also referred to as *speckle dystrophy*, *François–Neeten’s dystrophy*, or *cornea en moucheté*.

## Genetics

This disorder is autosomal dominant, with mutation in the phosphoinositide kinase FYVE finger containing gene at locus 2q34.

## Ocular Manifestations

Patients have discrete, small, white-to-gray opacities, which may be solid in appearance or have clear centers, scattered throughout the stroma. The corneal epithelium and endothelium are uninvolved.

## Patient Presentation

Most patients are asymptomatic, although the occasional patient may be photophobic.

## Pathology

Histopathology shows distension of some keratocytes with membrane-bound vacuoles containing GAGs (staining with Alcian blue and colloidal iron) and complex lipids (staining with oil red O and Sudan black).<sup>43</sup> The epithelium and the endothelium are normal. Electron microscopy shows membrane-based inclusions with delicate granular material in some keratocytes.<sup>44</sup>

## Treatment

No treatment is necessary.

## POSTERIOR AMORPHOUS CORNEAL DYSTROPHY

## Genetics

This disorder is autosomal dominant, with deletion of chromosome 12q21.33-q22 coding for four small leucine-rich proteoglycans<sup>45</sup> that are thought to play roles in collagen fibrillogenesis and matrix assembly.

## Ocular Manifestations

Posterior amorphous corneal dystrophy is a rare disorder, dominantly inherited, and defined by the presence of central and peripheral, deep corneal, gray, broad sheets of opacification.<sup>46</sup> Those with centrop peripheral changes were flat and hypermetropic, whereas those with less severe peripheral form were less hypermetropic and had keratometry readings above 41.<sup>47</sup> Iridocorneal adhesions have been reported.<sup>48</sup> The disorder appears to be nonprogressive, which has prompted the recommendation that this entity be considered a dysgenesis rather than a dystrophy.<sup>49</sup>

## Patient Presentation

Patients often present in their first decade, but vision is minimally affected.

## Pathology

Histopathological evaluation has shown irregular disorganization of the corneal lamellae anterior to Descemet’s membrane, with lipid deposition in the cytoplasm of some keratocytes.<sup>50</sup> Electron microscopy shows abnormal keratocytes and abnormally oriented collagen fibers, with disorganization of the posterior stromal lamellae.<sup>50</sup> A report described a case where subepithelial deposits and a thick collagenous layer posterior to Descemet’s membrane were found.<sup>51</sup>

## Treatment

No treatment is necessary.

## CONGENITAL STROMAL CORNEAL DYSTROPHY

Congenital stromal corneal dystrophy is present at birth and nonprogressive, so it better fits the category of congenital anomalies. Nonetheless, it is referred to as a dystrophy and resembles many of the other dystrophies.

## Genetics

This disorder is autosomal dominant, with a truncating mutation in the decorin (*DCN*) gene at locus 12q21.

## Ocular Manifestations

Congenital hereditary stromal dystrophy is a very rare disorder that is characterized by the presence of bilateral feathery or flaky, white, diffuse stromal clouding, most prominent in the central cornea. The corneal epithelium is normal, and no corneal edema occurs. The opacification is present at birth and is nonprogressive. Without treatment, visual acuity is reduced significantly, and nystagmus may ensue.

## Differential Diagnosis

The differential diagnosis includes congenital corneal edema (from congenital hereditary endothelial dystrophy), congenital glaucoma, and posterior polymorphous dystrophy. The absence of epithelial edema and the presence of normal corneal thickness and intraocular pressure, however, exclude these. Corneal haze from metabolic disorders usually is less evident at birth, increases over time, and is associated with systemic findings. In congenital stromal corneal dystrophy, no known systemic abnormalities have been found.

## Pathology

Histopathology reveals normal epithelium and Bowman’s layer, whereas the stroma shows separation of lamellae with layers of normal fibrillar arrangement separated by loosely packed layers of irregular and amorphous arrayed collagen, shown to be accumulated decorin material.<sup>52</sup> The collagen fibrils are about half the normal diameter. The normally banded anterior portion of Descemet’s membrane lacks bandings, but the posterior portion of Descemet’s membrane and the endothelium are normal.<sup>53</sup>

## Treatment

Treatment consists of DALK, usually with good outcomes.

## Diseases of the Corneal Endothelium

4.21

Noel Rosado-Adames, Natalie A. Afshari

**Definition:** Diseases affecting the innermost layer of the cornea, which is in charge of regulating the hydration state of the corneal stroma.

## Key Features

- Bilateral presentation.
- Corneal clarity affected (variable degree).
- Hereditary pattern.

## Associated Features

- Key clinical features on slit-lamp examination.
- Severe cases usually require corneal transplantation.

## INTRODUCTION

The effects of external trauma and of ophthalmic and systemic disease on human corneal endothelium are best understood by first reviewing the anatomy and physiology of the adult human endothelium. A comprehensive review of this material can be found in Chapter 4.1.

## FUCHS' DYSTROPHY

## Introduction

Fuchs' endothelial corneal dystrophy (FD) is a bilateral, noninflammatory, progressive loss of endothelial cells that results in corneal edema and reduction of vision. Its key features include the presence of central guttae, folds in Descemet's membrane, stromal edema, and microcystic epithelial edema. Corneal endothelial degeneration is the primary defect that leads to the development of corneal edema. Associated features include prominent corneal nerves, stromal opacification, recurrent corneal erosions, female gender predominance, and familial predisposition.

## Epidemiology and Pathogenesis

FD is the most common corneal dystrophy to require keratoplasty, accounting for approximately 3.1% of all penetrating keratoplasties (PKPs) and 47.1% of all endothelial keratoplasties in the United States in 2015.<sup>1</sup> The genetic basis of FD is complex and heterogeneous, demonstrating variable expressivity and incomplete penetrance.<sup>2</sup> FD is likely to be complex in etiology, with genetic as well as environmental factors playing a role in its pathogenesis.<sup>3</sup> A significant variation occurs in expressivity between males and females, with a 3–4:1 female/male ratio recorded at the time of keratoplasty.<sup>4</sup> It is equally common among white and black patients who undergo keratoplasty but is relatively rare in Asian patients.<sup>5</sup>

Development of guttae and the onset of symptoms are more common in middle age.<sup>6</sup> Patients with FD are believed to have an increased incidence of open-angle glaucoma.<sup>7</sup> Short axial length, shallow anterior chamber, and angle-closure glaucoma also have been seen in conjunction with FD.<sup>8</sup> FD has been associated with keratoconus.<sup>9–11</sup> The progressive loss of endothelial cell function is primary in nature rather than secondary to any alteration in aqueous humor flow rate<sup>12</sup> or constituency.<sup>13</sup> Endothelial dysfunction is mainly a result of a reduction in sodium, potassium–adenosine

triphosphatase ( $\text{Na}^+, \text{K}^+$ -ATPase) pump activity,<sup>14</sup> which leads to a reduction in ion flux across the endothelium.<sup>11</sup> Molecular biological studies of corneal buttons from patients with FD suggest that apoptosis may play an important role in endothelial cell degeneration.<sup>15</sup> Recent studies have demonstrated an oxidant–antioxidant imbalance in FD cells, which, in turn, leads to oxidative DNA damage and apoptosis.<sup>16</sup>

Several genetic loci have been identified in patients with FD.<sup>3</sup> The first genetic locus was mapped to chromosome 13, called *Fuchs' corneal dystrophy locus 1* (FCD1).<sup>17</sup> Subsequently, three other loci, FCD2,<sup>18</sup> FCD3,<sup>19</sup> and FCD4,<sup>20</sup> were mapped to chromosomes 18, 5, and 9, respectively. Additionally, other reports have provided evidence for potential linkage to chromosomes 1, 7, 15, 17, and X by genome-wide linkage analysis.<sup>21</sup>

Multiple causal genetic mutations have been linked to FD. Mutations in the ion cotransporter encoded by the *SLC4A11* gene, also associated with congenital hereditary endothelial dystrophy, have been linked to the development of FD.<sup>22,23</sup> Additionally, mutations in the transcription factor *TCF8* gene, also associated with posterior polymorphous corneal dystrophy, have been identified in patients with FD.<sup>20</sup> A third causal gene for FD, *LOXHD1*, was identified on chromosome 18.<sup>24</sup> This gene has been associated with the development of progressive hearing loss in humans.

A strong association has been discovered between FD and trinucleotide repeats (TNRs) in the transcription factor 4 (*TCF4*) gene in chromosome 18.<sup>25–28</sup> This gene encodes the E2-2 transcription factor, which is involved in cellular growth and differentiation.<sup>25</sup> Expansion of TNR lead to messenger RNA (mRNA) missplicing, which leads to RNA toxicity.<sup>26</sup> TNR expansion in *TCF4* of more than 50 is highly specific for FD.<sup>27</sup> Changes to the endothelial barrier function, a known event in the development of FD, was identified as a key biological process influenced by the missplicing events.<sup>28</sup>

Mutations in the gene *COL8A2* that codes for the  $\alpha_2$ -chain of type VIII collagen have been reported in patients with an early onset endothelial dystrophy that was previously considered an early form of FD.<sup>29</sup> Recent studies suggest that the endothelial dystrophy linked to mutations in *COL8A2* represents a disease that is phenotypically distinct from FD.<sup>2</sup>

## Ocular Manifestations

The earliest slit-lamp finding in FD is the presence of focal excrescences of extracellular matrix in Descemet's membrane, called guttae (cornea guttata). In the earliest stages of this disease, the guttae first emerge in the central corneal endothelium (Fig. 4.21.1). Guttae are not specific to FD and may be seen in asymptomatic patients and in the setting of both uveitis and nonspecific superficial keratopathies. Up to 11% of eyes in patients older than age 50 years have guttae.<sup>30</sup> Pathologically identical lesions in peripheral Descemet's membrane are known as Hassall–Henle warts and are part of the normal aging process (see Chapter 4.22).

The guttae initially appear on specular reflection as scattered, discrete, isolated dark structures, smaller than an individual endothelial cell.<sup>31</sup> An associated fine pigment dusting may be observed within the central endothelium. At this stage, referred to as *stage 1*, the patient's vision usually is normal, and the stroma and epithelium are uninvolved.<sup>3,30</sup> Over time, these individual excrescences increase in number, enlarge, and fuse with adjacent guttae to disrupt the normal endothelial monolayer's specular reflection.<sup>31</sup> This produces a roughened surface with a specular reflection similar to beaten metal in appearance. Eventually, this process expands from the center of the cornea to involve the corneal periphery. As the disorder progresses, the endothelial monolayer becomes attenuated in thickness, with an increase in average cell size (polymegathism), a decrease in the percentage of hexagonal shaped cells, and an increase in the coefficient of variation in cell size (pleomorphism). In the last stages of the dystrophy, effacement of the endothelium results in overlying stromal edema. At this

**Fig. 4.21.1** Slit-Lamp View of Fuchs' Dystrophy (FD). Note the guttae on the image of the endothelium reflected on the speculum.

**Fig. 4.21.2** Specular Photomicrograph of Fuchs' Dystrophy (FD). Note dark areas that represent guttae adjacent to areas of enlarged endothelial cells. (Spacing of grid 0.1 mm.)

point, the endothelium becomes more difficult to observe using conventional specular microscopy, but it may still be visualized using confocal microscopy.<sup>31</sup>

As endothelial function progressively declines, the fluid accumulated in the stroma during nighttime lid closure is removed at a reduced rate, which results in significant stromal edema upon awakening.<sup>32</sup> This heralds the onset of *stage 2*.<sup>3,30</sup> Patients note blurred vision, glare, and colored halos around lights. Initially, the stromal edema is localized in front of Descemet's and behind Bowman's membrane.<sup>33</sup> Eventually, the entire stroma swells, taking on a ground-glass appearance. With the increase in corneal thickness, the posterior stroma and Descemet's membrane are thrown into folds. Vision at this time is variable.

With progressive endothelial dysfunction, bulk fluid flow across the cornea results in microcystic and bullous epithelial edema. This development represents *stage 3* of the disease.<sup>3,30</sup> With involvement of the epithelial layer, the optical quality of the tear-air interface is severely degraded, which produces a profound reduction in vision. With the onset of epithelial edema, basal adhesion complexes become disrupted to produce recurrent corneal erosions. As a slit-lamp marker of recurrent epithelial sloughing, duplication of basement layers occurs, which creates fingerprint and map changes.

If erosions are prominent, a vascular pannus between epithelium and Bowman's membrane may be induced and results in an anterior stromal haze, with further reduction in vision, representing *stage 4* of the disease.<sup>3</sup> However, the associated secondary fibrotic layer produced within the pannus often reduces or eliminates the painful recurrent epithelial erosions experienced by the patient. With the increase in stromal edema, glycosaminoglycans elute from the stroma,<sup>34</sup> causing disorganization of the collagen fibrils, which contributes to additional stromal opacification.

## Diagnosis and Ancillary Testing

The earliest observable change suggestive of FD is the presence of guttae on slit-lamp examination (see Fig. 4.21.1). Specular microscopy provides endothelial cell counts, as well as a photographic record that can be a useful educational aid for the patient (Fig. 4.21.2). Subtle stromal edema can be observed using sclerotic scatter techniques. Corneal pachymetry documents increased corneal thickness. As the disease progresses, more obvious signs may develop, which include folds in Descemet's membrane, stromal haze, microcystic and bullous epithelial edema, subepithelial fibrosis, and pannus formation. When corneal opacification precludes specular microscopy, confocal microscopy can be used to image the endothelium and obtain reliable endothelial cell counts.<sup>31,32</sup>

## Differential Diagnosis

Differential diagnosis includes posterior polymorphous corneal dystrophy, congenital hereditary endothelial dystrophy, aphakic or pseudo-phakic bullous keratopathy, and Hassall-Henle bodies. No associated systemic diseases exist.<sup>3,30</sup>

**Fig. 4.21.3** Characteristic Wart-Like Bumps Present Within Descemet's Membrane. (A) Periodic acid-Schiff stain. (B) Scanning electron microscopy shows this better. (Courtesy Dr. R. C. Eagle, Jr.)

## Pathology

Light microscopy findings include a thickened Descemet's membrane, which may be laminated in appearance with buried guttae, guttae on the surface, or devoid of guttae but thickened (Fig. 4.21.3).<sup>4</sup> The endothelial layer is attenuated. Electron microscopy in FD shows characteristic thickening of Descemet's membrane caused by the deposition of an additional posterior banded layer (PBL), posterior to the posterior nonbanded layer. The PBL is markedly thickened and contains abnormally deposited

collagen and the classic posterior excrescences, guttae.<sup>3</sup> The production of this morphologically abnormal Descemet's membrane serves as a marker for a dysfunctional endothelium.<sup>35</sup>

## Treatment

Early stages of the disease may be managed medically, temporizing the need for a keratoplasty. Medical management includes the use of hypertonic solutions or ointments and decreasing ambient humidity. If intraocular pressure (IOP) is above 20 mm Hg (2.67 kPa), attempts to lower it may reduce the force that drives fluid into the stroma. Treatment measures for painful erosions include hypertonics, bandage contact lenses, anterior stromal puncture, and conjunctival flaps.

With progressive corneal edema refractory to medical management, keratoplasty usually is offered. PKP was traditionally performed for the treatment of advanced cases.<sup>36</sup> If the patient shows signs of visually significant cataracts, keratoplasty may be combined with cataract extraction.<sup>37</sup> In recent years, endothelial keratoplasty, including Descemet's stripping automated endothelial keratoplasty (DSAEK or DSEK) and Descemet's membrane endothelial keratoplasty (DMEK), has been performed as an alternative to conventional full-thickness corneal transplantation for the treatment of endothelial disorders.<sup>38–42</sup> In fact, endothelial keratoplasties represented 92% of the total keratoplasties performed in 2015 in patients with FD.<sup>1</sup> The DSAEK procedure involves replacing the diseased endothelium and deep stroma with a posterior lamellar disc of tissue, including donor corneal endothelium, Descemet's membrane, and posterior corneal stroma. DMEK involves replacing the diseased tissue with just the donor endothelium and Descemet's membrane. Both DSAEK and DMEK have been demonstrated to be superior to PKP in terms of earlier visual recovery, postoperative refractive outcomes, wound- and suture-related complications, and intraoperative and late suprachoroidal hemorrhage risk.<sup>40,43</sup> Studies have reported faster visual rehabilitation and better best corrected visual acuity with DMEK compared with DSAEK.<sup>44</sup> With DMEK, patients also had a lower rate of endothelial rejection (1%) at 2 years compared with DSAEK (9%) and PKP (17 %).<sup>45</sup>

## Course and Outcome

Long-term outcomes of patients with FD undergoing PKP have shown that graft clarity approached 90%, and approximately 60% of patients achieved 20/40 (6/12) or better visual acuity 5 years after transplantation.<sup>35</sup> Results after DSAEK have shown that average best-corrected visual acuity (BCVA; mean 9 months after surgery) ranged from 20/34 to 20/66.<sup>40</sup> One year after DMEK surgery, patients had an average BCVA of 20/24, with 98% of patients achieving 20/30 or better.<sup>46</sup> Reports of graft survival rates at 5 years for DMEK and DSAEK were similar to those reported for PKP in patients with FD (95%, 95%, and 93% respectively).<sup>41,47</sup>

## CONGENITAL HEREDITARY ENDOTHELIAL DYSTROPHY

### Introduction

First described by Maumenee<sup>48</sup> in 1960, congenital hereditary endothelial dystrophy (CHED) is but one of the many causes of bilateral corneal clouding in full-term infants and usually requires keratoplasty. Key features of this autosomal dominant or recessive condition are a corneal thickness 2–3 times normal, normal IOP, and normal corneal diameter. Associated features are corneal pannus, nystagmus, and esotropia.

### Epidemiology and Pathogenesis

Prevalence, incidence, and gender distribution for this disorder are unknown. The onset is usually at birth in a term infant; corneal clouding may be maximal at birth or progress over a period of years. Family pedigree studies support that autosomal dominant (CHED1) and recessive (CHED2) forms exist, as well as sporadic occurrences. Autosomal recessive inheritance is associated with bilateral corneal edema without photophobia but with nystagmus that is present at birth.<sup>49</sup> Autosomal dominant inheritance is associated with the progressive onset of corneal edema 1–2 years post partum with photophobia but without nystagmus.<sup>49</sup> Autosomal dominant and autosomal recessive forms of CHED have been linked to chromosome 20, mapped to the loci 20p11.2-q11.2 and 20p13, respectively.<sup>50</sup> Mutations in the *SLC4A11* gene in chromosome 20 have been highly associated with the

development of autosomal recessive CHED.<sup>50</sup> A related X-linked endothelial dystrophy has been described in males that clinically resembles CHED very closely.<sup>51</sup>

CHED is believed to result from abnormal neural crest cell terminal induction during the late term to perinatal period. At this time, failure to complete final differentiation of the endothelial monolayer occurs, which results in a dysfunctional endothelium.<sup>52</sup> This dysfunctional endothelium is believed to have faulty growth regulation mechanisms that lead to accumulation of a functionally abnormal and structurally exaggerated form of posterior nonbanded Descemet's membrane.<sup>53</sup>

## Ocular Manifestations

The usual presentation is bilateral, symmetrically edematous, cloudy corneas evident at birth or early in the postnatal period.<sup>49</sup> Examination reveals the corneas to have a diffuse gray-blue, ground-glass coloring.<sup>49</sup> Corneal thickness is 2–3 times normal and often greater than 1 mm centrally. Both IOP and horizontal corneal diameter are normal. Rarely, CHED is associated with glaucoma and should be considered if corneal opacification fails to resolve after normalization of IOP.<sup>54</sup>

Closer examination reveals the texture of the epithelial surface to be irregular, with a diffuse pigskin-like roughness.<sup>49</sup> Occasionally, discrete white dots may be seen in the stroma. In areas where stromal opacification is less dense, Descemet's membrane appears gray, and on specular reflection may have a *peau d'orange* texture.<sup>49</sup> The endothelial layer may or may not be visualized. A fine corneal pannus may be seen, as well as low-grade inflammation.

## Diagnosis

A tentative diagnosis usually is possible when examination under anesthesia demonstrates typical bilateral stromal opacification, gross corneal thickening, normal horizontal diameter, normal IOP, and absence of breaks in Descemet's membrane.

## Differential Diagnosis

Differential diagnosis includes congenital glaucoma without buphthalmos, posterior polymorphous corneal dystrophy, macular stromal dystrophy, mucopolysaccharidosis, intra-uterine infection, and birth trauma from forceps. Harboyan's syndrome is an entity defined as CHED accompanied by progressive, sensorineural hearing loss.<sup>55,56</sup> This disorder has been linked to the *SLC4A11* gene mutation.<sup>56</sup>

## Pathology

Light microscopy shows epithelial atrophy with basal cell hydrops, subepithelial calcification or fibrosis, patchy loss of Bowman's membrane, and variable vascularization or spheroidal degeneration of the stroma.<sup>53</sup> Descemet's membrane is thickened, often with discrete laminations. The endothelial layer is attenuated.<sup>53</sup>

## Treatment

If the edema is stationary and mild, use of hypertonics and desiccating measures may be employed. Usually, however, these patients require keratoplasty because of the bilateral nature of the corneal edema. Keratoplasty in infants and children is a high-risk procedure and is technically difficult, and the long-term prognosis for graft clarity is worse than it is for adults. No definitive clinical guidelines have emerged with regard to the timing of surgical intervention, as a result of significant heterogeneity in disease severity, follow-up periods, and patient ages at both diagnosis and surgery, among the few published studies.<sup>57</sup> Delayed PKP (after age 12 years) may offer better graft outcomes and visual prognosis in patients with CHED, even in the presence of nystagmus, according to a publication.<sup>58</sup> DSAEK has been performed in recent years as a therapeutic alternative for CHED. DSAEK performed in eyes with CHED has allowed rapid restoration of corneal clarity while minimizing intraoperative and postoperative complications normally associated with pediatric PKP.<sup>59</sup>

The decision regarding surgery may be difficult because despite significant corneal haze and absence of a red reflex, patients often seem to see much better than expected.<sup>60</sup> If patients maintain good fixation with normal alignment, surgery may be delayed; loss of fixation or development of nystagmus may lead to earlier intervention.<sup>60</sup>

## Course and Outcome

In one large study, during a mean follow-up period of over 70 months, 69% of eyes retained full graft clarity. Postoperative visual acuity improvement of 1 or more Snellen lines was seen in 5 of 10 eyes in which the patients were old enough for accurate assessment of visual acuity; however, just four of these 10 eyes attained a visual acuity of 20/200 or better.<sup>61</sup> First graft survival rates range from 25% at 3 months in earlier studies to 62%–90% at 2–3 years in more recent series.<sup>57,60,61</sup>

Results from a small series of patients older than age 12 months who underwent DSAEK revealed that BCVA of 20/40 or better was achieved in 8 of the 9 patients, and visual acuity of 20/70 was achieved in the remaining patient. In the infant group, the three patients who had DSAEK were able to “fix and follow” after the procedure.<sup>59</sup>

## POSTERIOR POLYMORPHOUS CORNEAL DYSTROPHY

### Introduction

First described in 1916 by Koeppe, this rare dystrophy has a clinical spectrum that ranges from congenital corneal edema to late-onset corneal edema in middle age. Many cases are subclinical—the majority of patients have good vision and only subtle slit-lamp and specular micrographic abnormalities. Posterior polymorphous corneal dystrophy (PPCD) is a bilateral autosomal dominant disorder characterized by polymorphic posterior corneal surface irregularities with variable degrees of corneal decompensation. Key features consist of the following:

- Vesicular, curvilinear, and placoid irregularities found on slit-lamp examination
- Rounded dark areas with central cell detail that produce a doughnut-like pattern on specular microscopy
- Epithelial-like transformation of endothelium on histological examination
- Reduced vision from the corneal edema.

Associated features are iridocorneal adhesions, peripheral anterior synchiae, glaucoma, and a tendency to recur in graft patients. Some of these features overlap with iridocorneal endothelial (ICE) syndrome, Peters' anomaly, and Axenfeld–Rieger syndrome, suggesting that PPCD may be part of a broader spectrum of disorders united by abnormalities of terminal neural crest cell differentiation.<sup>62,63</sup> PPCD associated with posterior amyloid degeneration of the cornea, keratoconus, and Alport's syndrome has been reported.<sup>62,64,65</sup>

### Epidemiology and Pathogenesis

The prevalence of this rare disorder in the general population is unknown. This autosomal dominant condition presents with variable genetic penetrance and expressivity.<sup>66,67</sup> PPCD has been linked to three chromosomal loci: (1) PPCD1 (OMIM 122000) on chromosome 20p11.2-q11.2; (2) PPCD2 (OMIM 609140) on chromosome 1p34.3–p32.3; and (3) PPCD3 (OMIM 609141) on chromosome 10p11.2.<sup>67</sup> Specific genes at each locus have been identified, but there is some controversy regarding the role of these genes in the pathogenesis of this condition.<sup>68–74</sup> Mutations in the homeobox gene *VSX1* in PPCD1 were demonstrated in PPCD families,<sup>69,70</sup> but other studies did not replicate these results.<sup>70,71</sup> Reports have associated the *COL8A2* gene within the PPCD2 locus, coding for the  $\alpha_2$ -chain of type VIII collagen, with PPCD,<sup>29,74</sup> as well as contributing to the pathogenesis of an early-onset endothelial corneal dystrophy. The contribution of this gene has been questioned as additional studies have failed to identify similar mutations within analyzed PPCD cohorts.<sup>74–76</sup> Studies investigating a candidate gene at the PPCD3 locus demonstrated disease-causing mutations in the zinc finger E-box binding homeobox 1 gene *ZEB1*, previously known as *TCF8*.<sup>77–81</sup> The *ZEB1* gene has the strongest association to PPCD based on linkage, association, and familial segregation analyses.<sup>81</sup>

The pathogenesis of PPCD is attributed to focal metaplasia of endothelial cells into a population of aberrant keratinized epithelial-like cells.<sup>62,65</sup> Immunohistochemical analyses of these transformed cells show that they contain antigens and cytokeratins that usually are associated with epithelial cells.<sup>82</sup> The transformation of a single-cell layer of endothelium into a multilayered epithelium-like tissue is believed to be responsible for the loss of stromal deturgescence, the observed specular microscopic patterns, and the tendency toward synechiae formation.

**Fig. 4.21.4** Slit-lamp appearance of vesicles in posterior polymorphous dystrophy. Note the small vesicular lesions on retroillumination. (Courtesy Dr. Richard Yee.)

**Fig. 4.21.5** Slit-Lamp Appearance of the Band Form of Posterior Polymorphous Dystrophy. Note the vertical serpentine band. (Courtesy Dr. Richard Yee.)

### Ocular Manifestations

The most common finding is isolated vesicles bilaterally, which appear as circular or oval transparent cysts with a gray halo, diameters in the range of 0.2–1 mm, at the level of Descemet's membrane, best viewed by retroillumination with a widely dilated pupil (Fig. 4.21.4).<sup>83,84</sup> The cysts may be few or many, widely separated or clustered close together to create confluent geographical patches. Less common are band-shaped or “snail track” areas, which typically have scalloped edges and are about 1 mm across (Fig. 4.21.5).<sup>83</sup> Their length can range from 2–10 mm.<sup>84</sup> In both vesicular and band presentations, the overlying stroma and epithelium are uninvolved, and vision is normal. The least common slit-lamp finding is placoid or diffuse endothelial involvement.<sup>83</sup> Patients who have placoid-type PPCD often present with reduced vision. Specular microscopy of the presenting lesions shows them to be sharply demarcated from uninvolved endothelium. In this presentation, Descemet's membrane and the posterior stroma are hazy, and usually areas of corneal edema and iridocorneal adhesions occur.<sup>84</sup>

On specular microscopy, the vesicles appear as circular dark rings around a lighter, although mottled, center in which cellular detail is evident.<sup>83–87</sup> These vesicles represent steep-sided, shallow depressions in the endothelium<sup>83</sup>; the steep sides correspond to the peripheral dark ring seen on specular reflection, and the depressed center corresponds to the lighter, mottled central portion (Fig. 4.21.6). Specular microscopy of the band-shaped areas shows them to be composed of a chain of overlapping vesicles, which create a shallow trench with scalloped borders

**Fig. 4.21.6 Specular Photomicrograph of Vesicles in Posterior Polymorphous Dystrophy.** Note the doughnut-like appearance of the vesicles. (Courtesy Dr. Richard Yee.)

that represent the edges of individual vesicles that have fused.<sup>83</sup> Patients with PPCD may exhibit broad-based iridocorneal adhesions and peripheral anterior synechiae. These most often are seen in corneas with placoid areas of involvement.<sup>84</sup> Elevation of IOP refractory to medical measures is common in these patients. All patients who have PPCD have reduced endothelial cell counts compared with age-matched controls.<sup>83,85</sup>

## Diagnosis

The majority of patients are diagnosed with use of the slit lamp that helps visualize vesicular, band-like, or placoid areas on the posterior corneal surface. The diagnosis of PPCD in patients with corneal edema of unknown cause is based on light and electron microscopy of the excised buttons obtained during keratoplasty.

## Differential Diagnosis

Differential diagnosis includes tears in Descemet's membrane, interstitial keratitis, FD, and ICE syndrome (discussed in detail in Chapter 10.20). As in PPCD, endothelial cells in ICE syndrome may show epithelial characteristics, leading to speculation that they represent a spectrum of the same disease.<sup>63</sup> No systemic associations exist except for rare reports of PPCD associated with Alport's syndrome.

## Pathology

Light microscopy shows pits in the posterior corneal surface, which correspond to the vesicles seen on slit-lamp examination. Descemet's membrane in these areas is attenuated, and the endothelium may be multilayered.<sup>86,87</sup> In other areas, Descemet's membrane appears multilayered, of variable thickness, and with attenuation or loss of endothelium. Discontinuities in Descemet's membrane with anterior migration of cells to form slit-like structures or clefts in pre-Descemet's stroma have been described.<sup>64</sup> Scanning electron microscopy of keratoplasty buttons may show a striking

juxtaposition of normal-appearing endothelial cells adjacent to epithelial cell-like areas that show myriad surface microvilli.<sup>86,87</sup> Transmission electron microscopy shows multilayered cells that contain numerous desmosomes and intracytoplasmic filaments.<sup>86,87</sup> Cell culture studies demonstrate features similar to cultured epithelial cell lines.<sup>87</sup>

## Treatment

The majority of patients require no treatment; those with corneal opacification are offered keratoplasty. Traditionally, penetrating keratoplasty was performed in this group of patients. Recent reports have shown the implementation of endothelial keratoplasty with positive results.<sup>88,89</sup>

## Course and Outcome

In the majority of patients, PPCD is believed to be a nonprogressive type of dystrophy, usually without vision impairment. Those patients who require keratoplasty appear to be at risk for recurrence of this dystrophy in the grafted cornea,<sup>90-92</sup> as well as for the development of glaucoma.<sup>87</sup> It is thought that the genesis of this behavior is the epithelial-like transformation and subsequent migration of host endothelium, which causes the endothelium to encroach on the donor corneal tissue and host angle structures.<sup>87</sup>

# Corneal Degenerations

Maria A. Woodward, Shahzad I. Mian, Alan Sugar

# 4.22

**Definition:** Secondary deterioration or deposition in the cornea, distinct from dystrophies.

## Key Features

- Common.
- Bilateral usually.
- Typically does not affect vision.

## Associated Features

- Increased prevalence with age.
- Often associated with chronic light exposure.
- May occur after inflammation.
- Not inherited.

## INTRODUCTION

Degenerations of the cornea are common conditions that, in most cases, have relatively little effect on ocular function and vision. These conditions occur with increasing age, as a result of past inflammation, and with long-term toxic effects of environmental exposure. Unlike corneal dystrophies, corneal degenerations are not inherited, may be unilateral or bilateral, and often are associated with corneal vascularization. Degenerations tend to involve the peripheral cornea and may overlap the limbus and conjunctiva.

The conditions that occur in the corneal periphery are discussed first, followed by the conditions that occur more centrally. This is an arbitrary division as many conditions, such as spheroidal degeneration or band keratopathy, can be found in either or both locations.

## CORNEAL ARCUS (ARCUS SENILIS)

Corneal arcus presents as a gray-to-white, occasionally yellow, band of peripheral corneal opacification. It consists of fine dots, has a clear zone (clear interval of Vogt) between it and the limbus, and has a diffuse central border with a sharper peripheral border (Fig. 4.22.1). It begins superiorly and inferiorly and spreads to involve the entire periphery. Deposits begin in the deep stroma with progression to involve the superficial stroma. Arcus is almost always bilateral but can be asymmetric in unilateral carotid vascular disease (decreased arcus) or chronic ocular hypotony (increased arcus).<sup>1</sup>

Arcus is the most common corneal degeneration. In men, the frequency increases with age and occurs in essentially all men older than 80 years of age. The presentation is delayed by 10 years in women.<sup>1</sup>

Arcus deposits consist of extracellular corticosteroid esters of lipoproteins, mostly of low density. Lipid material leaks from limbal capillaries with central flow being limited because of a functional barrier to the flow of large molecules in the cornea.<sup>2,3</sup>

Strong evidence exists for an association with increased plasma cholesterol and low-density lipoprotein cholesterol, particularly when it occurs in men younger than 50 years (arcus juvenilis). Men with arcus juvenilis have a fourfold increased relative risk of mortality from coronary heart disease and cardiovascular disease. Arcus in young men, therefore, is a useful clinical indication for the need for lipid and cardiovascular evaluation.<sup>4</sup> Young patients who have arcus have an increased risk for type

**Fig. 4.22.1 Arcus Senilis.** (A) Corneal arcus in an older man. (B) Histological section shows that the lipid is concentrated in the anterior and posterior stroma as two red triangles, apex to apex, with the bases being Bowman's and Descemet's membranes, both of which are infiltrated heavily by fat (red staining), as is the sclera.

IIa dyslipoproteinemia but a decreased risk for type IV.<sup>5</sup> In older patients, arcus does not correlate with mortality.<sup>6</sup>

## LIPID KERATOPATHY

Lipid keratopathy may be peripheral, central, or diffuse and is similar in appearance to arcus. It occurs mainly in a secondary form, but rarely may be seen in a primary form. Primary lipid keratopathy has features of a corneal dystrophy, is usually bilateral, and the central lipid, often with cholesterol crystals, may severely decrease vision.<sup>7</sup>

Secondary lipid keratopathy appears as a white or yellow stromal deposit separated by a narrow, clear zone from corneal stromal neovascularization<sup>8</sup> (Fig. 4.22.2). It often is denser than arcus and may appear as a circular deposit at the end of long-standing stromal vessels. It can follow corneal edema, as in hydrops.<sup>9</sup> Histological evaluation shows that the material consists of intra- and extracellular lipids.<sup>10</sup>

Lipid deposition may occur secondary to systemic lipid processing disorders. Defects in esterification of cholesterol and in lipoprotein scavenging have been implicated in lecithin cholesterol acetyltransferase (LCAT)

**Fig. 4.22.2 Dense Lipid Keratopathy.** Note the central and peripheral lipid deposits that followed zoster keratitis with vascularization.

**Fig. 4.22.3 Vogt's Limbal Girdle.** The fimbriated peripheral corneal opacity is visible in the 9 o'clock position (arrow).

deficiency, Fish-eye disease, and Tangier disease. Disorders of high-density lipoprotein function appear to allow accumulation of cholesterol centrally within the cornea.<sup>1</sup>

### VOGT'S WHITE LIMBAL GIRDLE

Vogt<sup>11</sup> was the first to describe two types of limbal girdle—white, arc-like opacities in the cornea central to the limbus in the 3 o'clock and 9 o'clock positions. Type I is a mild, early form of calcific band keratopathy. Type II lacks a peripheral clear zone and consists of fine, white radial lines, located nasally more often than temporally (Fig. 4.22.3). The prevalence of this condition increases with age to essentially 100% in those older than 80 years of age.<sup>12</sup>

Histologically, Vogt's limbal girdle type II is made up of hyperelastotic and hyaline deposits peripheral to Bowman's layer, similar to those seen in a pingueculum and pterygium.

### SENILE CORNEAL FURROW DEGENERATION

Furrow degeneration is a painless bilateral thinning of peripheral cornea. A peripheral corneal furrow can occur between corneal arcus and the limbus in older adults.<sup>11</sup> Often the clear area may appear to be furrowed, but it was considered to be falsely thinned by Vogt.<sup>11,13</sup> Rarely, true thinning with no inflammation, vascularization, or induced corneal astigmatism can occur in this region. Furrow degeneration does not require any therapy, but the location and degree of thinning should be evaluated when considering location for cataract incisions.

## TERRIEN'S MARGINAL CORNEAL DEGENERATION

This condition is described in Chapter 4.17.

### PERIPHERAL CORNEAL GUTTAE

The corneal endothelium undergoes degeneration with age, as manifested by a decreasing endothelial cell density<sup>14</sup> and thickening of the posterior, nonbanded layer of Descemet's membrane.<sup>15</sup> Degenerating endothelial cells produce localized nodular thickening of Descemet's membrane, known as *guttae*. The relationship of central guttae to Fuchs' corneal endothelial dystrophy (FD) is discussed elsewhere (see Chapter 4.21). Peripheral guttae, known as Hassall–Henle warts, are visible in normal adult corneas and are thought to be truly degenerative and unrelated to FD. They are not associated with functional corneal changes.

### CALCIFIC BAND KERATOPATHY

Band keratopathy is a common corneal degeneration that can occur at any age, presenting in the central or peripheral cornea. It most commonly occurs secondary to chronic corneal diseases, particularly uveitis, advanced glaucoma, keratitis, or trauma; primary idiopathic forms rarely occur. Band keratopathy can present secondarily with elevated serum calcium or phosphate in systemic diseases, including sarcoidosis, hyperparathyroidism, vitamin D toxicity, metastatic neoplasm to bone, and chronic renal failure with secondary hyperparathyroidism. Researchers have described a toxic form resulting from mercurial preservatives in pilocarpine and an acute form after intracameral tissue plasminogen activator injection.<sup>16</sup> In children, band keratopathy may be the presenting sign of chronic uveitis as a result of juvenile idiopathic arthritis. Band keratopathy may occur after localized corneal damage from intraocular silicone oil and phosphate forms of corticosteroids.<sup>17,18</sup>

Histologically, calcium is deposited as the hydroxyapatite salt in the epithelial basement membrane, basal epithelium, Bowman's layer,<sup>19</sup> and anterior stroma. The mechanism of calcium deposition in the cornea is unknown but occurs primarily in the exposed area of the cornea. Deposition of calcium may result from the precipitate tears leave when they evaporate or because the exposed cornea is at a lower pH than other areas.<sup>19</sup> The most severely affected areas are the middle and inferior thirds of the cornea, which are the areas of greatest exposure to the atmosphere.

Corneal calcium deposits as a horizontal band and begins near the corneal periphery (Fig. 4.22.4). As the deposits move centrally, the band has clear void circles where Bowman's layer is traversed by nerve endings. The deposits begin as a gray haze and can become densely white with a rough, pebbly surface.

Patients can have symptoms of pain, foreign body sensation, recurrent corneal erosions, and decreased vision. The rate of development and progression of disease is variable.<sup>20</sup> If band keratopathy causes persistent pain or decreased vision, corneal surgery is indicated. The surgery involves removing the epithelium over the deposits, applying 0.05 mol/L disodium ethylenediaminetetraacetic acid to chelate the calcium and dissolve it, and using a brush or surgical blade to remove remaining calcium.<sup>21</sup> The process can take a few minutes to an hour, depending on the density of the calcium. Excimer laser phototherapeutic keratectomy also may be used to remove the calcium deposits.<sup>22</sup>

### SPHEROIDAL DEGENERATION

Spheroidal degeneration may occur in the cornea or the conjunctiva. Other names for this degeneration include climatic droplet keratopathy, hyaline degeneration, and local designations, such as Labrador keratopathy.<sup>23,24</sup> Spheroidal degeneration occurs as a primary corneal form, a secondary corneal form, and a conjunctival form. The frequency of this degeneration increases with age and varies with geographical location—occurring most often in areas that have high sunlight exposure (snow or sand) and high winds. It is twice as prevalent in men as in women. The prevalence varies from 6% in England to greater than 60% in Labrador. It is thought to be a result of ultraviolet light exposure and may be associated with blue-light exposure.<sup>25,26</sup> Other risk factors are drying of the cornea and repeated corneal trauma. Secondary forms can occur with corneal scars, lattice dystrophy, and glaucoma.

Spheroidal degeneration presents as fine droplets, yellow or golden in color, beneath the epithelium (Fig. 4.22.5). The droplets appear oily, although they are not composed of lipid. In the primary form, droplets

**Fig. 4.22.4 Band Keratopathy.** (A) Calcium deposits in the cornea of a 13-year-old with juvenile rheumatoid arthritis. (B) A fibrous pannus (P) is present between the epithelium (E) and a calcified Bowman's membrane (CB). Some deposit is also present in the anterior corneal stroma (S).

**Fig. 4.22.5 Spheroidal Degeneration.** Central spheroidal droplets in the cornea of an eye that is blind as a result of glaucoma.

begin peripherally and advance centrally between the palpebral fissures. As the condition advances, the droplets become larger, more nodular, and more opaque lifting the central corneal epithelium. Three stages of the primary form have been described:

- Grade I—fine shiny droplets are present only peripherally without symptoms.
- Grade II—the central cornea is involved and vision  $\geq 20/100$  (6/30).
- Grade III—there are large corneal nodules and vision  $\geq 20/200$  (6/60).

These forms are always bilateral. Grade III disease may be rapidly progressive and lead to corneal ulceration with secondary bacterial infection.<sup>27</sup>

**Fig. 4.22.6 Hudson–Stähli Line.** Thin horizontal brown line in inferior cornea of a healthy 57-year-old male. (Courtesy the photography department, WK Kellogg Eye Center, University of Michigan.)

Histologically, deposits appear as extracellular amorphous globules, which may coalesce in Bowman's layer and spill over to anterior stroma. These globules consist of a protein material with elastotic features, as in pingueculae. The source of the protein is unknown, but it has been postulated to result from the action of ultraviolet light on proteins from limbal vessels.<sup>23,28</sup>

The majority of cases of spheroidal degeneration are asymptomatic. Patients with visual loss may be treated with superficial keratectomy and, when necessary, lamellar or penetrating keratoplasty.

## IRON DEPOSITION

Iron deposition occurs in the corneal epithelium in several clinical situations. The prototype is the Hudson–Stähli line, which is located at the junction of the middle and lower thirds of the cornea (Fig. 4.22.6). It is yellow-brown in color, curves downward at its center, and is usually about 0.5 mm wide and 1–2 mm long. It is seen most clearly in blue light as a black line. Similar iron deposition occurs in keratoconus at the base of the cone (Fleischer's ring), around filtering blebs (Ferry's line), central to a pterygium (Stocker's line), around Salzmann's nodules, within the margin of corneal grafts, between radial keratotomy scars, and following laser in situ keratomileusis (LASIK) or intrastromal corneal ring placement.<sup>29,30</sup> The source of the iron is unknown but most likely comes from the tear film. It is postulated that altered tear flow secondary to distorted corneal shape is a factor in the formation of these lines and that epithelial migration patterns affect the shape of the Hudson–Stähli line.

Histologically, the iron is deposited intracellularly in corneal epithelial cells as a ferritin-like material, possibly hemosiderin.<sup>31</sup> Iron lines do not affect vision or cause any symptoms and thus require no treatment.

Coats' white ring is an iron deposition that occurs in the anterior portion of Bowman's layer. It appears as a tiny ring of white dots, most often inferiorly, and is asymptomatic.<sup>32</sup> It is thought to result from previous iron deposition by a corneal foreign body.

## CROCODILE SHAGREEN

Crocodile shagreen appears as anterior or posterior polygonal opacities in the corneal stroma that occur as a consequence of aging. Crocodile shagreen was first described by Vogt.<sup>11</sup> The pattern resembles that of crocodile skin and is thought to be related to the oblique insertion of the collagen lamellae that constitute the corneal stroma<sup>33,34</sup> (Fig. 4.22.7). In vivo confocal microscopy demonstrates the mosaic pattern of the collagen lamella.<sup>35</sup> Crocodile shagreen is a very common, although frequently subtle, finding in older patients. The anterior form is more common than the posterior form, with the opacities in posterior crocodile shagreen presenting more peripherally and, thus, may be indistinguishable from corneal arcus.

Familial forms of posterior crocodile shagreen have been described in a dominant juvenile form and in a form associated with X-linked megalocornea. Central cloudy dystrophy of François appears to be similar and is likely not a true dystrophy (see Chapter 4.20).

**Fig. 4.22.7 Posterior Crocodile Shagreen.** A mottled, gray pattern is visible in the central cornea.

**Fig. 4.22.8 Salzmann's Nodular Degeneration.** Severe corneal involvement in an elderly woman.

## CORNEA FARINATA

First described by Vogt, cornea farinata occurs in the corneas of older patients, is without symptoms, and is recognized as an incidental finding.<sup>11</sup> The corneal opacities in this condition are fine, dust-like dots of white or gray color in the deep central stroma, just anterior to Descemet's layer.<sup>36</sup> The Latin word *farinata*, meaning "like wheat flour," refers to the appearance of the dots. The bilateral deposits are best visualized by slit-lamp retroillumination. The cause of the condition is unknown. The histology suggests that the deposits may be composed of lipofuscin in stromal keratocytes.<sup>37</sup>

## SALZMANN'S CORNEAL DEGENERATION

Salzmann's corneal degeneration may occur at any age but is primarily a condition of older adults. It has been associated with phlyctenular keratitis, interstitial keratitis, vernal keratitis, trachoma, or Thygeson's superficial punctate keratitis. It also occurs with no history of prior corneal disease. It typically develops several decades after previous keratitis. It may be unilateral or bilateral and occurs more often in women than in men.

Salzmann's corneal degeneration appears as white-to-gray or light-blue nodules that elevate the epithelium in the superficial corneal stroma (Fig. 4.22.8). The nodules may be single or in clusters, often at the edge of old corneal scars. Each nodule is about 0.5–2 mm in diameter, not vascularized, and separated from other nodules by clear cornea. The onset of the lesions is gradual, over many years, during which time they increase in both size and number.<sup>38</sup> They may decrease vision by encroaching upon

**Fig. 4.22.9 Corneal Keloid Recurrence.** A central, elevated, fibrous opacity is present centrally. The photo was taken 6 months after superficial keratectomy for the original lesion.

the central cornea or by altering the corneal shape. They may be associated with recurrent corneal erosions.<sup>39</sup>

Histologically, thinned epithelium overlies hyalinized avascular collagen. Bowman's layer is damaged or focally absent and replaced by material that is similar to basement membrane.<sup>40</sup> Usually, evidence of old keratitis is seen in the surrounding stroma. In vivo confocal microscopy studies show irregular epithelium and activated keratocytes in the area of the nodule.<sup>41,42</sup> Many patients who have peripheral nodules are asymptomatic and require no treatment. If vision is altered or if recurrent erosions are frequent, the nodules may be removed by peeling from the underlying stroma or excimer laser phototherapeutic keratectomy.<sup>23</sup> Recurrences have been found after all forms of treatment.<sup>43</sup>

## CORNEAL KELOIDS

Corneal keloids are uncommon and result from progressive growth of fibrous tissue on the cornea that outgrows the original boundaries. They typically appear months or years following trauma, surgery, or inflammatory processes. The appearance is consistent with an elevated gray-white mass involving the entire stroma or isolated nodules (Fig. 4.22.9).

Histologically, poorly arranged collagen fibers, myofibroblasts, and blood vessels are noted in early stages. In later stages, compaction of collagen and reduction in vascularity and cellularity occurs. Significant keloids may be treated with superficial keratectomy, lamellar keratoplasty, or penetrating keratoplasty.<sup>44,45</sup>

## CORNEAL AMYLOID DEGENERATION

Amyloid is a group of hyaline proteins deposited in tissues in a variety of systemic and localized conditions. Familial localized amyloidosis is seen in the cornea as lattice, Avellino's, and gelatinous drop-like corneal dystrophies.

The degenerative forms of amyloid seen in the cornea and conjunctiva are secondary, localized, and nonfamilial. These occur as nonspecific corneal deposits that follow corneal trauma, keratitis, or chronic intraocular inflammation. Usually, they are diagnosed with histopathology after removal of nonspecific corneal opacities.<sup>46</sup>

A specific form of corneal amyloid degeneration has been described as polymorphic amyloid degeneration.<sup>47</sup> It is characterized by the presence of deep central corneal stromal glass-like deposits that often indent Descemet's layer (Fig. 4.22.10). They are bilateral, generally occur after age 50 years, and do not affect vision. Histologically, they appear similar to lattice dystrophy deposits composed of amyloid. The cause is unknown.

Another stromal deposition with features of both spheroidal degeneration and amyloid deposition has been called *climatic proteoglycan stromal keratopathy*.<sup>48</sup> This has been described in Saudi Arabian patients with risk factors similar to those of spheroidal degeneration. The patients have bilateral, horizontal, oval, central anterior stromal, ground-glass haze that consists of both proteoglycan and amyloid on histopathology. This condition does not usually affect vision.<sup>48</sup>

**Fig. 4.22.10 Polymorphic Amyloid Degeneration.** Glassy, fine deep corneal deposits in the central cornea of an older woman.

# Dry Eye Disease

Michael H. Goldstein, Naveen K. Rao

# 4.23

**Definition:** A multifactorial disease of the ocular surface characterized by deficient tear production and/or excessive tear evaporation, leading to loss of homeostasis of the tear film.

## Key Features

- Symptoms: ocular and conjunctival irritation.
- Ocular surface disruption.

## Associated Features

- Possible autoimmune disease (i.e., Sjögren's syndrome).
- Possible conjunctival or lid abnormalities.
- Blurred or unstable vision.

## INTRODUCTION

Dry eye disease (DED), also known as dry eye syndrome (DES) or keratoconjunctivitis sicca (KCS), is characterized by ocular irritation and visual disturbance resulting from alterations of the tear film and ocular surface.<sup>1-10</sup> The effects of DED can vary from minor inconvenience to rare sight-threatening complications. Although the diagnosis of DED traditionally has focused on inadequate secretion or aqueous tear deficiency, the tear film is a complex and delicately balanced unit dependent on the normal function of several distinct components.<sup>10-13</sup> Current treatment is heavily weighted toward supplementation, stimulation, preservation of aqueous tears, or treatment of ocular surface inflammation, which is satisfactory for many patients. DED, however, often involves multiple deficiency states, which, when disregarded, can result in treatment failure and frustration for both the patient and the physician. Currently, a large unmet need still exists for better treatment options for patients with DED.

## EPIDEMIOLOGY

Estimating the prevalence of DED is complicated by the absence of consensus on a single reliable diagnostic test. Several population-based epidemiological studies have utilized questionnaires to assess prevalence of dry eye symptoms. American and Australian studies have revealed a prevalence of 5%–16%, whereas Asian studies have revealed a higher prevalence of approximately 27%–33%.<sup>14-25</sup>

## PATHOGENESIS

### Normal Physiology

The stratified tear film is composed of mucin, aqueous, and lipid components. The mucin layer consists of high-molecular-weight glycoproteins closely adherent to an inherently hydrophobic surface epithelium and its glycocalyx. Mucin provides a smooth, hydrophilic surface permitting even distribution of the overlying aqueous layer. Its primary source is conjunctival goblet cells with a small contribution from surface epithelial cells.<sup>26,27</sup> Comprising the largest volume of the tear film, the aqueous is secreted by the main lacrimal gland, the accessory glands of Krause and Wolfring, and, minimally, a transudate of the conjunctival vessels and cornea. Consisting primarily of water, it also contains electrolytes (sodium [Na], potassium [K], chloride [Cl]) and proteins, including epidermal growth factor, immunoglobulins (IgA, IgG, IgM), lactoferrin, lysozyme, and other cytokines.<sup>28,29</sup> These components likely play both a protective and a homeostatic role for the ocular surface. Last, meibomian glands (MGs) secrete a lipid layer,

containing chiefly sterol esters and wax monoesters.<sup>3,30</sup> Although only 0.1- $\mu$ m thick, the lipid layer serves to stabilize the tear film by increasing surface tension and retarding evaporation.

The tear layer maintains a smooth surface for optical clarity, lubricates to facilitate eyelid blink, and offers protection against ocular infection.<sup>11</sup> Average tear flow is about 1.2- $\mu$ m/minute.<sup>31</sup> Blinking serves to periodically distribute tears evenly over the ocular surface and encourages both secretion and mechanical drainage of tears through the lacrimal drainage system. Regulation likely involves both neuronal and hormonal pathways. Direct innervation of the lacrimal gland, MGs, and goblet cells has been demonstrated, with M3 class cholinergic receptors predominating in the lacrimal gland.<sup>32</sup> Although estrogen has little effect on tear secretion, it may have a supportive role on the ocular surface.<sup>33</sup> Androgens appear to have a positive effect on the secretion of both aqueous and lipid tears.<sup>34,35</sup>

## Pathophysiology

Reduced aqueous tear flow and increased evaporation of the aqueous component of tears leads to hyperosmolarity. Tear hyperosmolarity damages the ocular surface epithelium and sets off a cascade of inflammatory pathways that leads to apoptotic cell death, loss of goblet cells, and deficient mucus production, with resultant tear film instability. Tear film instability, in turn, leads to increased evaporation. Implicated cytokines include mitogen-activated protein (MAP) kinases, nuclear factor- $\kappa$ B (NF- $\kappa$ B), interleukin-1 (IL-1), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), and matrix metalloproteinases (MMP-9, in particular).<sup>36-38</sup> In the early stages of DED, inflammation and mechanical irritation stimulates reflex secretion from the lacrimal gland and increased blink rate. Over time, damage to the ocular surface leads to reduction in corneal sensation and impaired reflex tearing.<sup>10</sup> In advanced cases, chronic conjunctival damage can lead to metaplasia and keratinization.

## Diagnosis and Classification

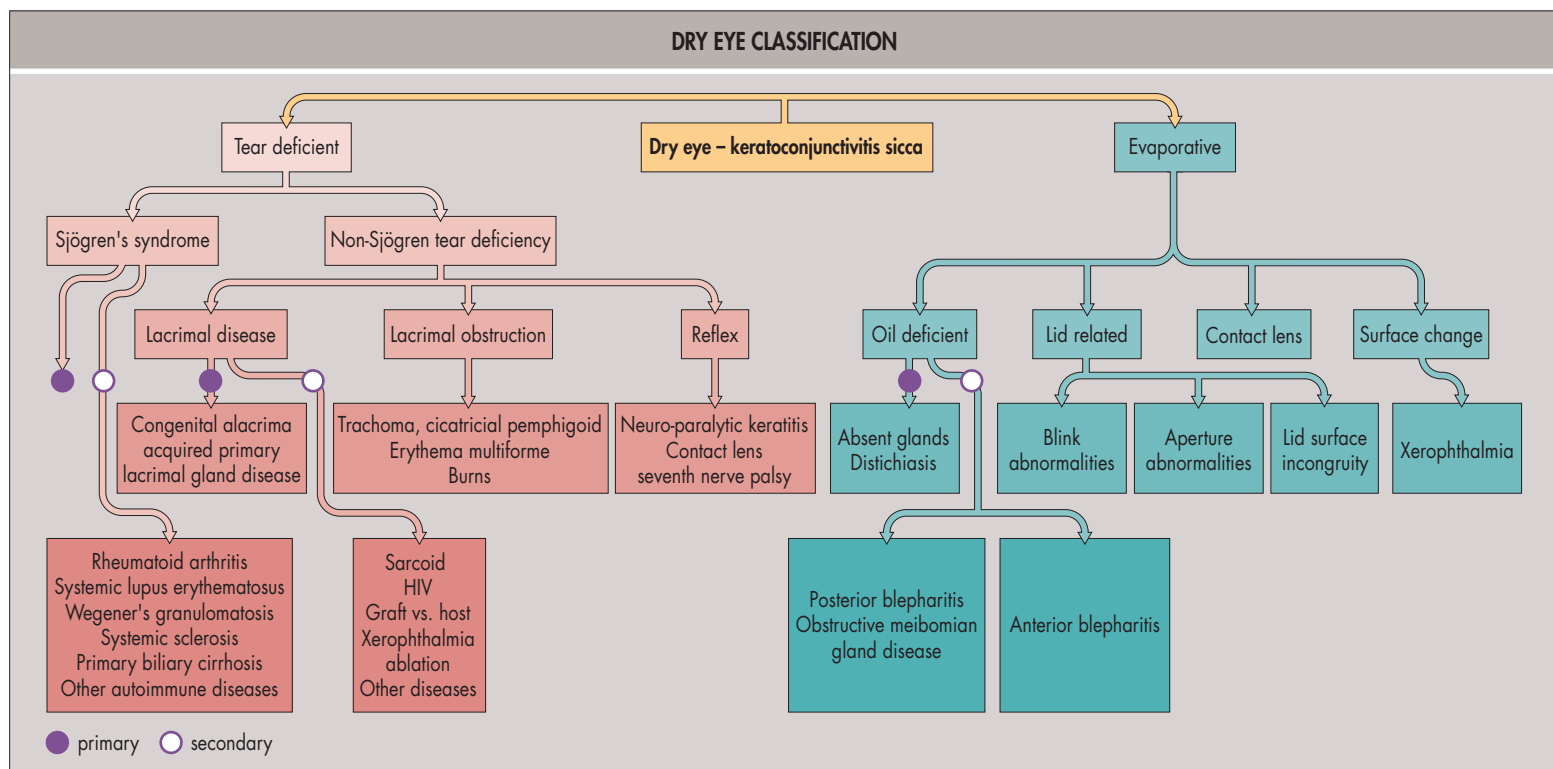

The 2017 report for the International Dry Eye Workshop (DEWS II) was a 2-year effort with 12 subcommittees made up of 150 experts from 23 countries. The DEWS II report updated the definition of dry eye as follows: "Dry eye is a multifactorial disease of the ocular surface characterized by a loss of homeostasis of the tear film, and accompanied by ocular symptoms, in which tear film instability and hyperosmolarity, ocular surface inflammation and damage, and neurosensory abnormalities play etiological roles."<sup>39</sup> The new definition emphasizes the multifactorial nature of DED, where loss of homeostasis of the tear film is the central pathophysiological concept. It also recognizes the role of neurosensory abnormalities in the development of DED. This definition continues to incorporate concepts introduced in the first DEWS report that DED results in ocular discomfort, visual disturbance, and tear film instability with potential damage to the ocular surface.<sup>10</sup> This definition encompasses all the clinical entities associated with systemic disease, as well as idiopathic DED.

A classification system algorithm for dry eye is depicted in Fig. 4.23.1. The effect of the environment on an individual's risk of developing dry eye also is considered. Low blink rate,<sup>40,41</sup> wide lid aperture,<sup>42-44</sup> aging,<sup>45-47</sup> low androgen levels,<sup>48,49</sup> high estrogen levels,<sup>50,51</sup> and systemic drugs affect the so-called milieu interieur.<sup>10</sup> Low relative humidity, air conditioning, air travel,<sup>52</sup> high wind velocity, and other occupational environmental factors, such as video display terminal use<sup>53</sup> affect the so-called milieu exterieur.<sup>10</sup>

## Aqueous Tear-Deficient Dry Eye

Sjögren described KCS in 1933.<sup>54</sup> Consequently, defective lacrimal tear secretion is subdivided into non-Sjögren's tear deficiency (NSTD) and

**Fig. 4.23.1** Dry eye disease classification. (With permission from Lemp MA. The 1998 Castroviejo Lecture. New strategies in the treatment of dry-eye states. *Cornea* 1999;18:625–32.)

Sjögren's syndrome tear deficiency (SSTD). NSTD has no association with systemic autoimmune disease, which is a cardinal feature of SSTD.

### Non-Sjögren's Tear Deficiency

NSTD can occur from primary lacrimal gland deficiencies, secondary lacrimal gland deficiencies, obstruction of lacrimal gland ducts, or reflex hyposcretion.<sup>10</sup> Primary lacrimal gland deficiencies include age-related DED, congenital alacrima, and familial dysautonomia (Riley–Day syndrome). The most common form of NSTD is age-related DED, which is associated with ductal and interacinar fibrosis and obstruction within the lacrimal gland, possibly as a result of low-grade chronic inflammation.<sup>55–57</sup> Congenital alacrima is a rare cause of DED in youth, resulting from primarily absent or hypoplastic lacrimal glands. Familial dysautonomia is an autosomal recessive multisystem disorder, in which generalized pain insensitivity accompanies absence of both emotional and reflex tearing. Defective sympathetic and parasympathetic innervation of the lacrimal gland and defective sensory innervation of the ocular surface occur.<sup>10</sup>

Secondary lacrimal gland deficiency from infiltration and damage to the lacrimal gland in benign lymphoepithelial lesion of Godwin ("Mikulicz's disease"), lymphoma, sarcoidosis, hemochromatosis, amyloidosis, human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), and graft-versus-host disease all can result in DED.<sup>58–61</sup> Surgical or radiation-induced destruction or denervation of lacrimal tissue can result in secondary lacrimal deficiency.<sup>58</sup> Secondary obstruction of the lacrimal gland ducts can occur with trachoma,<sup>61</sup> ocular cicatricial pemphigoid, mucous membrane pemphigoid,<sup>62–64</sup> erythema multiforme/Stevens–Johnson syndrome,<sup>65</sup> chemical burns, and thermal burns.<sup>66</sup>

Reflex hyposcretion of tears can be conceptually divided into reflex sensory block (damage to the afferent arm) and reflex motor block (damage to the efferent, or secretomotor arm). Reflex sensory block occurs with any reduction in ocular surface sensation and leads to decreased reflex-induced lacrimal secretion and decreased blink rate, which increases tear evaporation.<sup>10,67</sup> Causes of decreased ocular surface sensation leading to dry eye include topical anesthetic use,<sup>68</sup> contact lens wear,<sup>69,70</sup> diabetes mellitus,<sup>17,71–74</sup> aging, and neurotrophic keratitis.

As shown by studies utilizing topical anesthesia, interruption of the afferent stimulus of tear production, or sensory loss (denervation), results in decreased tear secretion and reduced blink rate.<sup>68,75</sup> Damage to afferent sensory fibers occurs after incisional corneal surgery (penetrating or anterior lamellar keratoplasty, radial keratotomy, and limbal cataract incision) and after damage to the first division of the trigeminal ganglion from trauma, tumor, and herpes simplex or zoster, resulting in reduced tear production. Laser-assisted in situ keratomileusis (LASIK) and photorefractive

**TABLE 4.23.1** Medications Associated With Dry Eye Disease

Mechanism of Action	Class	Medications
Anticholinergic	Antimuscarinics	Tolterodine tartrate (Detrol) Scopolamine
	Antihistamines (sedating compounds are associated with greater dryness)	Chlorpheniramine (Chlor-Trimeton) Diphenhydramine (Benadryl) Promethazine (Phenergan)
	Antiparkinsonian	Benzotropine (Cogentin) Trihexyphenidyl (Artane)
	Antidepressants	Amitriptyline (Elavil)
	MAO inhibitors	Nortriptyline (Pamelor) Imipramine (Tofranil) Doxepin (Sinequan) Phenelzine
	Antipsychotics	Chlorpromazine (Thorazine) Thioridazine (Mellaril) Fluphenazine (Prolixin)
Antiadrenergic	Alpha-agonists	Clonidine (Catapres)
	Beta-blockers	Methyldopa (Aldomet) Propranolol (Inderal) Metoprolol (Lopressor)
Diuretic	Thiazide	Hydrochlorothiazide
Other	Nonsteroidal anti-inflammatory drugs	Ibuprofen (Advil) Naproxen (Naprosyn, Aleve)
	Cannabinoids	Marijuana

keratectomy resulting in decreased corneal sensation and blink rate are recognized as precipitating causes of dry eye.<sup>67,76–79</sup> Systemic medications are a common source for the inhibition of efferent lacrimal gland stimulation through anticholinergic activity or decreased secretion through systemic dehydration (Table 4.23.1).<sup>80</sup> Although DED has been reported in association with menopause, estrogen supplementation has not been shown to have a beneficial effect.<sup>50,81</sup> Alterations in other hormones, especially androgens, which also are reduced during menopause, have been implicated.

### Sjögren's Syndrome Tear Deficiency

Sjögren's syndrome is a clinical condition of aqueous tear deficiency combined with dry mouth. The syndrome is classified as primary (patients

without a defined connective tissue disease) or secondary (patients who have a confirmed connective tissue disease).<sup>82–84</sup> Primary SSTD refers to aqueous tear deficiency combined with symptoms of dry mouth, presence of autoantibodies to Ro(SSA) or La(SSB) antigens, decreased salivary secretion, and presence of lymphocytic foci on minor salivary gland biopsy. Secondary SSTD is associated with rheumatoid arthritis, systemic lupus erythematosus, polyarteritis nodosa, Wegener's granulomatosis, systemic sclerosis, primary biliary cirrhosis, and mixed connective tissue disease.<sup>10,83</sup> Both subtypes of SSTD feature progressive lymphocytic infiltration of the lacrimal and salivary glands and can be associated with severe and painful ocular and oral discomfort. The pathogenesis of the tear deficit in SSTD is infiltration of the lacrimal gland by B and CD4 lymphocytes (with some CD8 lymphocytes) and by plasma cells, with subsequent fibrosis.

Revised American-European consensus diagnostic and classification criteria for Sjögren's syndrome were published in 2002.<sup>83</sup> One point is given for at least one positive response or positive result in each of the following categories:

- **Ocular symptoms**—daily dry eye symptoms for more than 3 months, ocular irritation, use of artificial tears more than three times per day.
- **Oral symptoms**—daily dry mouth symptoms for more than 3 months, presence of swollen salivary glands, frequent drinking of liquids to aid in swallowing.
- **Ocular signs**—Schirmer's test I (without anesthetic)  $\leq 5$  mm in 5 minutes, Rose Bengal score  $\geq 4$  according to the van Bijsterveld scoring system.
- **Histopathology**—biopsy of minor salivary gland showing inflammation with lymphocytic foci.
- **Oral signs**—reduced salivary flow  $\leq 1.5$  mL in 5 minutes, parotid sialography showing salivary duct dilation without obstruction, salivary scintigraphy showing signs of decreased saliva production.
- **Autoantibodies**—presence of anti-Ro(SSA) antibody, presence of anti-La(SSB) antibody.

For a diagnosis of primary Sjögren's syndrome, either four of the six categories (including either histopathology or autoantibodies) or three of the four objective categories (ocular signs, histopathology, oral signs, and autoantibodies) must be met. For diagnosis of secondary Sjögren's syndrome, in patients with a defined connective tissue disease, the presence of one symptom (ocular or oral) plus two of the three objective categories (ocular signs, histopathology, and oral signs) must be met.

## Evaporative Dry Eye Disease

Excessive evaporation that occurs in specific periocular disorders can cause dry eye disease with or without concurrent aqueous tear deficiency. Evaporation leads to both loss of tear volume and a disproportionate loss of water, resulting in tear hyperosmolarity. Environmental conditions such as high altitude, dryness, or extreme heat accelerate evaporative tear loss even in normal eyes. Causes of evaporative DED can be intrinsic (disease affecting lid structures or dynamics) or extrinsic.<sup>10</sup>

## Meibomian Gland Disease and Blepharitis

Meibomian gland dysfunction (MGD) leads to both decreased secretion and abnormal composition of the tear film lipid layer. The abnormal composition leads to MG blockage and reduced effectiveness in the tear film. The resulting ocular surface and eyelid inflammation perpetuates a cycle of inflammation, scarring, hyperkeratosis, stenosis, and further MGD.

Often associated, bacterial colonization by normal lid commensals (*Staphylococcus aureus*, *Propionibacterium acnes*, and coagulase-negative staphylococci) acts directly by altering secreted lipids and indirectly by causing inflammation. Esters and lipases produced by these commensals act on secreted lipids in the tear film, producing soaps that manifest as "meibomian foam."<sup>85,86</sup> An association also is seen with dermatological conditions, such as seborrheic dermatitis, atopic dermatitis, and acne rosacea, a disorder resulting in vascular dilation, telangiectasias, and plugging of sebaceous glands of both facial and eyelid skin. Secondary MGD can occur with use of 13-*cis* retinoic acid (isotretinoin) for treatment of acne,<sup>87–89</sup> ingestion of polychlorinated biphenyls in contaminated cooking oil,<sup>90–92</sup> and with cicatricial changes in conditions, such as chemical/thermal burns, trachoma, pemphigoid, erythema multiforme/Stevens-Johnson syndrome, acne rosacea, vernal keratoconjunctivitis, and atopic keratoconjunctivitis.<sup>10</sup> In simple MGD, the MG orifices remain anterior to the mucocutaneous junction, whereas in cicatricial MGD, MG orifices are drawn posteriorly onto the lid and tarsal mucosa.

## Exposure

Excessive exposure of the ocular surface leads to increased evaporative loss of tears; thus, any disorder that results in increased ocular exposure can cause evaporative DED. Psychological, psychiatric, mechanical, neurological, or traumatic impairment of eyelid function may result in impaired or reduced blinking, lagophthalmos, or an increased palpebral fissure width, resulting in an evaporative dry eye. Evaporative DED can be seen in thyroid eye disease secondary to proptosis or lid retraction.

## Mucin Deficiency

Local conjunctival damage from cicatrizing disease or surgical trauma results not only in aqueous tear deficiency but also in depopulation of mucin-producing goblet cells and creation of anatomical abnormalities of the conjunctiva leading to improper tear distribution. Although uncommon in incidence, trachoma, pemphigoid, erythema multiforme/Stevens-Johnson syndrome, and chemical and thermal burns can result in severe DED characteristically resistant to aqueous tear replacement therapy.

## Extrinsic Causes

Vitamin A deficiency can result in extensive goblet cell loss and dysfunction, leading to an unstable tear film and severe DED (xerophthalmia).<sup>93–96</sup> Preservatives in many eyedrops (especially benzalkonium chloride) can lead to ocular surface toxicity and a dry-eye state that may be reversible if eyedrops are switched to nonpreserved formulations. Contact lens wear is commonly associated with DED symptoms. Pre-lens tear film thinning time and pre-lens lipid layer thickness is reduced in contact lens wearers with DED symptoms, and may lead to higher evaporative loss.<sup>97</sup> Ocular allergies can cause a variety of corneal and conjunctival irregularities with decrease in tear film stability and consequent DED.

## OCULAR MANIFESTATIONS

Regardless of the cause, most forms of DED share similar symptoms, interpalpebral surface damage, tear instability, and tear hyperosmolarity. Typical complaints include burning, itching, foreign body sensation, stinging, dryness, photophobia, ocular fatigue, and redness. Although symptoms usually are nonspecific, careful attention to details will help refine the diagnosis.

Patients commonly describe a diurnal pattern of aqueous tear deficiency with progression of symptoms over the day and decompensation in particular environmental conditions, such as low humidity in airline cabins, climate control, and the use of video display terminals.<sup>53,98</sup> Conversely, nighttime exposure, floppy eyelid syndrome, and inflammatory conditions often present with worst discomfort upon awakening.

MGD creates an unstable tear film resulting in intermittent visual blurring and a gritty or sandy sensation. DED in diabetes and other corneal neuropathies may exhibit little or no discomfort and create high risk for keratolysis.

Common signs of DED include conjunctival injection, decreased tear meniscus, photophobia, increased tear debris, and loss of corneal sheen found more commonly in the exposed interpalpebral fissure. Paradoxical epiphora in DED is usually a result of reflex tearing. Greater risk for external infections exists secondary to decreased tear turnover and desiccation of the surface epithelium. Instability of the surface epithelium and disordered mucin production may lead to painful and recurrent filamentary keratitis. Although keratinization may occur uncommonly in chronic DED, vitamin A deficiency also should be suspected.

Patients who have SSTD tend to have more severe symptoms and more serious findings compared with NSTD patients. Sterile ulceration of the cornea in SSTD can be peripheral or paracentral; both thinning and perforation of these ulcers can occur (Fig. 4.23.2). Acute lacrimal enlargement may be seen in SSTD but should be differentiated from benign lymphoepithelial lesion of Godwin (Mikulicz's disease), which results from infiltration of the gland without surface findings.<sup>99</sup>

## DIAGNOSIS AND ANCILLARY TESTING

### Diagnostic Dye Evaluation

Fluorescein is a large molecule unable to traverse normal corneal epithelial tight junctions. In advanced DED, these junctions are disrupted, allowing characteristic diffuse subepithelial or punctate staining. Rose Bengal stain,

**Fig. 4.23.2** Patient (age 73 years) with rheumatoid arthritis and secondary Sjögren's disease.

**Fig. 4.23.3** Dry eye disease with Rose Bengal staining.

a derivative of fluorescein, in a 1% solution or impregnated strips, stains devitalized epithelial cells (Fig. 4.23.3).<sup>100</sup> Alternatively, lissamine green stains for cell death or degeneration, as well as cell-to-cell junction disruption, but does not irritate the eye.<sup>101</sup>

## Tear Film Stability

Tear film instability may be a result of either tear deficiency or evaporative DED. In the tear break-up time (TBUT) test, described by Norn and revised by Lemp and Holly, fluorescein dye is instilled and the time interval is measured between a complete blink to the first appearance of a dry spot in the precorneal tear film.<sup>102</sup> TBUTs shorter than 10 seconds indicate tear film instability.

## Measurement of Tear Production

The most common means of measuring tear production has been Schirmer's test, the details of which were first published in 1903.<sup>103</sup> Jones later advocated the use of topical anesthesia combined with a Schirmer's test strip for 5 minutes to reduce the stimulating effect of the filter paper strip—the “basal” tear secretion test.<sup>104</sup> Inconsistencies in its application limit repeatability in DED, but it still enjoys widespread use.<sup>105</sup> With these caveats in mind, the following general guidelines are recommended (when topical anesthesia is used): a 5-minute test that results in less than 5 mm of wetting confirms the clinical diagnosis of DED, and a result of 6–10 mm of wetting suggests DED.<sup>106</sup>

Hamano et al. developed the phenol red thread test to obviate the disadvantages of Schirmer's test by eliminating the need for anesthesia.<sup>107</sup> Three millimeters of a fine dye-impregnated 75-mm cotton thread is placed under the lateral one fifth of the inferior palpebral lid margin for

15 seconds; alkalinity changes its color to bright orange from tear contact. Asian populations show a lessened wet-length response with diminishing racial differences with advancing age.<sup>108</sup>

Hyperosmolarity is a common endpoint for all DED. Its measurement can be a sensitive and specific indicator.<sup>106</sup> Its use had previously been limited to specialized research centers because of the need for expensive equipment, but commercially available devices may now make this test more widely used in the clinic. Researchers also have sampled tears or ocular surface cells looking for inflammatory biomarkers, such as IL-1, IL-17, MMP-9, interferon- $\gamma$  (IFN- $\gamma$ ) and human leukocyte antigen–antigen D-related (HLA-DR). A qualitative commercial test currently is available to sample ocular surface tears for MMP-9 in the clinic. Other rarely performed tests for reduced tear function include fluorophotometry for decreased protein content, lysozyme levels, ocular ferning, impression cytology, and lactoferrin assays. Noninvasive imaging of the tear film using meniscometry, lipid layer interferometry, high-speed videography, optical coherence tomography, and confocal microscopy has been advocated as well.<sup>109–113</sup>

## Other Tests

Corneal sensation may be qualitatively assessed with a cotton wisp, but quantification requires an instrument, such as the Cochet–Bonnet aesthesiometer. The tear clearance test measures tear turnover with serial tear collection after instillation of a standardized volume of dye.<sup>105,114</sup> Serological tests, traditionally including antinuclear, anti-Ro, and anti-La antibodies, should be performed in patients suspected of having autoimmune DED. A recently launched commercial diagnostic test combines traditional biomarkers with novel, proprietary biomarkers to create a more accurate diagnostic test for patients suspected of having Sjögren's syndrome. A definitive diagnosis of Sjögren's syndrome requires minor salivary or, rarely, lacrimal gland biopsy.

Neither clinical presentation nor individual ancillary tests alone are sufficient for an accurate diagnosis of DED. Because of the therapeutic importance of appropriate categorization of patients, Pflugfelder et al. combined standard subjective examination with ancillary tests in the evaluation of patients with SSTD, NSTD, inflammatory MGD, and atrophic MGD.<sup>115</sup> Clinically important results were identified and compiled into an algorithm that helps differentiate patients with DED by using available tests (Fig. 4.23.4).

## TREATMENT

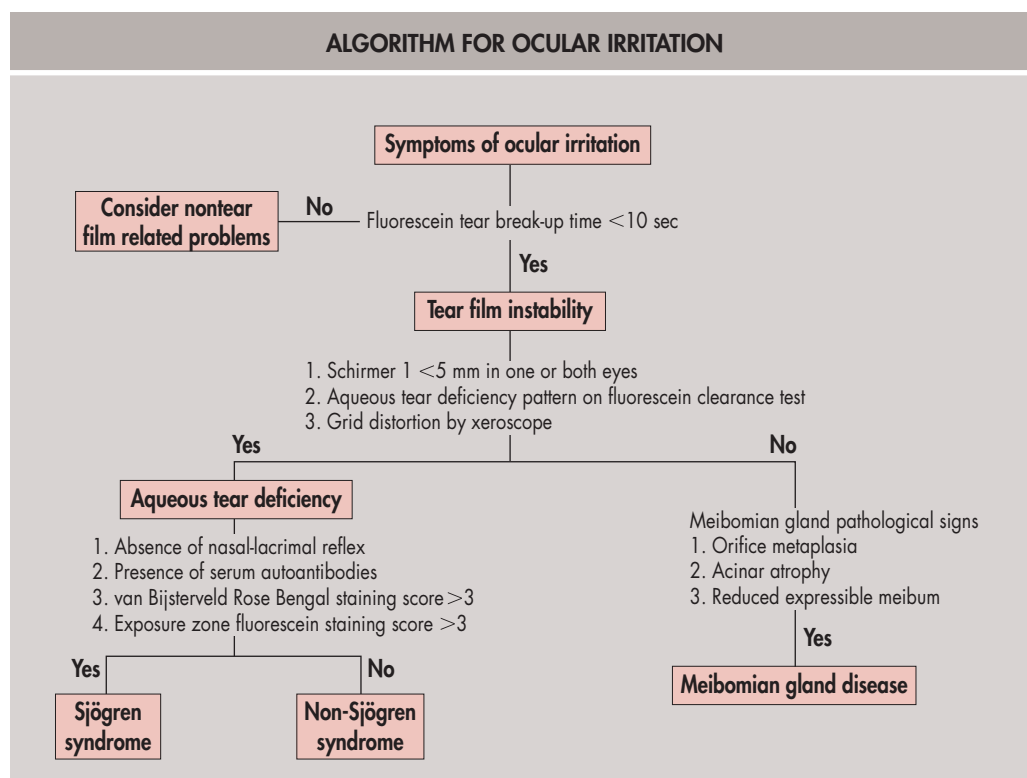

Significant advances have been made in treating the many facets of DED, but it remains a disorder of long-term maintenance rather than permanent cure. Current therapy focuses on restoring a normal ocular surface through tear supplementation as well as inhibition of aberrant inflammation seen in chronic DED. Since the tear film is a highly integrated unit, addressing each component is central to the successful treatment of DED.

## Aqueous Tear Deficiency

As the first line of treatment, artificial tears increase available tears and, through dilution, reduce tear hyperosmolarity. Commercial artificial tears differ in electrolyte composition, thickening agents (methylcellulose, hydroxypropyl methylcellulose, polyvinyl alcohol), physiological buffering, tonicity, and preservative system. Individual patient preferences involve such disparate concerns as cost, comfort, visual blurring, and ease of use. Preserved tears (i.e., benzalkonium chloride) can be toxic in moderate or severe DED, are poorly tolerated, and harmful. For patients with significant DED, single-dose, nonpreserved tear preparations are the mainstay of therapy with bottled tear products a reasonable alternative when preserved with relatively nontoxic compounds. These less toxic preservatives include polyquaternium-1, sodium chlorite, and sodium perborate.<sup>116</sup> Some artificial tear preparations are formulated to be hypo-osmotic, with the goal of balancing the hyperosmolarity of the tear film in DED. Artificial tear ointments are effective for longer-lasting control of symptoms, especially during sleep, but visual blurring limits their daytime usefulness. In addition, some ointments contain lanolin and parabens, which can be poorly tolerated by patients with severe DED. Autologous serum tears contain trophic factors and other proteins useful in ocular surface maintenance.<sup>116</sup> These can be useful as a preservative-free, biological tear substitute, but their preparation is labor intensive.

Punctal occlusion retards tear drainage, thereby increasing tear volume on the ocular surface and lowering tear osmolarity. Occlusion may be

**Fig. 4.23.4** Diagnostic algorithm for ocular irritation. (With permission from Pflugfelder SC, Tseng SC, Sanabria O, et al. Evaluation of subjective assessments and objective diagnostic tests for diagnosing tear-film disorders known to cause ocular irritation. *Cornea* 1998;17:38–56.)

achieved irreversibly by cauterization or semi-permanently with the use of nonabsorbable plugs. Occlusion with collagen plugs provides temporary relief (3 days to 6 months) and may identify those at risk for epiphora prior to permanent occlusion. Epiphora in the setting of one functional punctum is uncommon.

Secretagogues, agents that stimulate lacrimal gland secretion, require functional glandular tissue. Oral pilocarpine (Salagen) and cevimeline (Evovac) are M3 cholinergic agonists approved for use in dry mouth that also stimulate tear secretion.<sup>32,117,118</sup> Their effect tends to be greater in oral dryness rather than ocular dryness. Systemic cholinergic side effects, such as sweating reduce patients' acceptance. Various nutritional supplements are also touted for DED but without clear confirmation of their efficacy.

## Evaporative Dry Eye Disease

Primary treatment of MGD involves improving the quality and quantity of native MG secretions. Lid hygiene, in the form of warm compresses and lid massage, is effective in improving MG secretion. Several techniques, including the Lipiflow System, have been developed to help with expression of meibomian glands. Lid scrubs with dilute detergents decrease the seborrheic or bacterial load, thereby breaking the proinflammatory cycle of MGD. Systemic tetracyclines have been shown to decrease local inflammation and improve MG function after several weeks. The antibacterial effect also contributes to a decrease in meibomian lipid breakdown products in the tear film. Topical erythromycin or azithromycin applied to the eyelid margins are alternatives for patients who are unable to tolerate tetracycline derivatives. A number of lipid-like tear substitutes have become commercially available, which have been used with some success.<sup>119</sup>

Correction of eyelid abnormalities that increase exposure of the ocular surface, such as lower lid ptosis and lagophthalmos, can stabilize a decompensated ocular surface. In severe cases, a partial or complete tarsorrhaphy or a conjunctival flap may be necessary to prevent decompensation of the cornea. The use of humidifiers, moisture chambers, glasses, or goggles increases periorbital humidity and decreases surface evaporative pressure. New high-*Dk* (oxygen permeability), high-water-content contact lenses and new polymer lenses, accompanied by proper tear supplementation and hygiene, are effective in treating patients with DED with poor corneal wetting. In patients with severe DED, scleral contact lenses can promote lubrication and slow evaporation of tears from the ocular surface.

## Ocular Surface Inflammation

A common endpoint of all treatments of DED is not only prevention of ocular surface inflammation and its consequential cellular changes but

also restoration of the ocular surface. DED-induced ocular surface inflammation disrupts the epithelial and mucin layers, further exacerbating tear film breakdown. Suppression of inflammation creates a supportive environment for reversal of DED-induced cellular changes.<sup>120,121</sup> Topical cyclosporine A has been shown to increase tear production in a subset of patients through inhibition of lacrimal gland inflammation and suppression of DED-induced ocular surface inflammation.<sup>122–124</sup>

Lifitegrast 0.05% is the drug most recently (July 11, 2016) approved by the U.S. Food and Drug Administration to address DED and is the only therapy approved to treat both the signs and symptoms of DED. Lifitegrast is a topical anti-inflammatory drug that blocks the binding of intercellular adhesion molecule-1 (ICAM-1) to lymphocyte function associated antigen-1 (LFA-1) on the T-cell surface. Lifitegrast decreases inflammation by inhibiting T-cell recruitment and activation.<sup>125,126</sup>

Judicious use of low-dose topical corticosteroids has been shown to reduce inflammation and allow normal reparative mechanisms to restore the natural equilibrium of the ocular surface.<sup>127,128</sup> Use of topical corticosteroids in DED currently is limited because of concerns about adverse events with chronic use, such as glaucoma and cataract. Control of these reactive epithelial changes restores normal cell morphology, cell-to-cell interactions, and critical mucin production and clearly has a role in the global treatment of all forms of DED.

Essential fatty acids cannot be synthesized by humans and must be consumed in the diet. The typical Western diet contains a ratio of omega-6 to omega-3 fatty acids of approximately 25:1.<sup>114</sup> Omega-6 fatty acids are precursors to arachidonic acid and proinflammatory molecules, including prostaglandin E2 and leukotriene B4. Omega-3 fatty acids inhibit synthesis of these inflammatory mediators and decrease production of IL-1 and TNF- $\alpha$ .<sup>129,130</sup> Supplementing the diet with omega-3 fatty acids has been shown to decrease both signs and symptoms of DED.<sup>131</sup> Omega-3 fatty acids include eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), and alpha-linolenic acid (ALA). EPA and DHA are believed to be primarily responsible for the beneficial health effects of omega-3 fatty acids. Fish oil contains high levels of EPA and DHA, and flaxseed oil contains high levels of ALA. Although ALA is converted by the body into EPA and DHA, this process is not efficient; much higher quantities of flaxseed oil must therefore be consumed to achieve equivalent EPA and DHA levels from smaller quantities of fish oil.<sup>132,133</sup>

A number of drugs (mostly topical and a few systemic) are currently being evaluated in clinical trials aimed at providing new treatment options for patients with DED.<sup>134,135</sup> Success with this research should provide patients with many more treatment options in the future and has the potential to improve quality of life for patients suffering from DED.<sup>136</sup>

# Complications of Contact Lens Wear

Joshua S. Agranat, Deborah S. Jacobs

# 4.24

**Definition:** Inflammatory, metabolic, mechanical, or infectious events that are associated with contact lens use.

## Key Features

- Overall safety record of contact lenses is excellent.
- Low-Dk lenses, overnight wear, and poor lens care practices are modifiable risk factors for the development of contact lens–related problems.
- Patient education remains an important avenue for prevention of complications of contact lens wear.

## INTRODUCTION

In the United States, an estimated 40.9 million adults wear contact lenses, and nearly one third of them have experienced a contact lens–related complication requiring a visit to their doctors.<sup>1</sup> Although many contact lenses are managed by optometrists and opticians, some complications threaten sight and the long-term health of the eye, which makes it important that ophthalmologists are well informed about this problem.<sup>2–4</sup> This chapter will discuss toxic and allergic reactions, conditions reflecting metabolic challenge, corneal inflammatory events (CIEs), and microbial keratitis (MK). The long-term sequelae of these contact lens–related complications range from mild, self-limiting disease to vision loss even with proper treatment. Problems related to fit, comfort, and tolerance, including lens warpage, tight lens, dry eye, deposits, and mucin balls, are outside the scope of this chapter.

## TOXIC, ALLERGIC AND MECHANICAL REACTIONS

### Solutions

Toxic or allergic conjunctivitis may be caused by some components of the lens care system. The agents frequently responsible for toxic or allergic reactions are preservatives, disinfectants, surfactant and enzyme cleaners, and concentrated hydrogen peroxide. Allergic reactions are hypersensitivity reactions that occur after repeated exposure to the sensitizing antigen. In the past, thimerosal was a common offender, but sorbate and benzalkonium chloride are likely causes now.<sup>5</sup>

Patients with a toxic reaction experience immediate ocular discomfort and conjunctival injection with lens insertion. Toxic conjunctivitis can occur the first time the solution is used or may result from a buildup of the toxic component in the hydrogel material. Typically, patients have used the care system for 1 month or longer before symptoms of conjunctival injection and irritation develop. On examination, conjunctival hyperemia, follicles, superficial punctate keratitis, scattered fine infiltrates, and superior limbic keratoconjunctivitis may be seen (Fig. 4.24.1). Discontinuation of the solution results in resolution of symptoms, but if the symptoms and signs are severe, a short course of topical corticosteroids may be needed. When resuming lens wear, wearers of hydrogel lenses should replace their lenses, which may have absorbed the offending agent, but wearers of rigid gas-permeable (RGP) lenses may use the same lenses if they are thoroughly cleaned and rinsed. Incorrect use of solutions and cleaners can contribute to toxic reactions, especially with incomplete rinsing of surfactant cleaners or failure to neutralize peroxide solutions. Environmental chemical exposure, such as cosmetics and hair sprays, may also lead to toxic or allergic reactions when they contaminate lenses. Patients can be

**Fig. 4.24.1** This photo with fluorescein and cobalt lighting shows a diffuse superficial keratitis typical of solution toxicity.

switched to care systems with different preservatives or to daily disposable lenses to avoid solutions altogether.

There have been case reports of severe toxic reactions to contact lens use that resemble central toxic keratopathy syndrome—a constellation of corneal thinning and flattening, hyperopic shift, and marked stromal “mud crack” central opacity.<sup>6,7</sup> Treatment includes removal of the offending chemicals; use of preservative-free solutions; topical corticosteroid, if inflammation is severe; and a change to more frequent lens replacement and/or alternative lens material and care system.

### Giant Papillary Conjunctivitis

Giant papillary conjunctivitis (GPC), sometimes called *contact lens papillary conjunctivitis* (CLPC), was first reported in the 1970s and is thought to be a result of both mechanical irritation and immunological stimulation.<sup>8–11</sup> It is believed that a cell-mediated reaction to the antigens deposited on contact lenses causes trauma to the tarsal conjunctiva, exposing the antigens to the ocular immune system and initiating the reaction.<sup>9,12,13</sup> It should be noted that GPC has also been reported in those who do not wear contact lenses as a result of other causes of mechanical irritation, such as exposed sutures, extruded scleral buckles, foreign bodies, cyanoacrylate glue, ocular prostheses, and filtering blebs.<sup>14</sup> GPC is characterized by itching, burning, increased mucus production, foreign-body sensation, and papillae on the upper tarsus ranging from 0.3–2 mm<sup>14</sup> (Figs. 4.24.2, 4.24.3, 4.24.4). It is the most common complication of contact lens use.<sup>15</sup> Patients typically report increased deposits on lenses, which may be visible on examination. Papillae are a late finding and are not necessary for diagnosis.

Factors associated with GPC include duration of wear, hygiene, history of atopy/environmental allergy, and the fall and spring seasons.<sup>15–18</sup> Lens cornea fit, bacterial bioburden, history of adverse ocular events, race, and gender are not associated with GPC.<sup>19,20</sup>

The initial treatment for GPC is removal of the inflammatory stimulus via cessation of contact lens wear for 2–4 weeks. When resuming use, it may be helpful to decrease wear time, institute more frequent lens replacement, optimize lens hygiene with goal of reducing deposits, or prescribe a new lens material or design. Limited wear of daily disposable lenses is a

**Fig. 4.24.2** Early to moderate giant papillary conjunctivitis, highlighted with fluorescein dye.

**Fig. 4.24.3** As giant papillary conjunctivitis progresses, the papillae can grow to greater than 1 mm in size, and advanced lid changes may not resolve completely with treatment.

**Fig. 4.24.4** The use of fluorescein dye highlights the large papillae in this patient with advanced giant papillary conjunctivitis.

good way of reintroducing lens wear while minimizing antigen presentation. Adjunctive therapies for severe cases include topical mast cell stabilizers, used as initial treatment and for suppressive maintenance, and pulse regimen of topical corticosteroid, with appropriate monitoring. The role of topical immunomodulators, such as tacrolimus, has been reported.<sup>21</sup> GPC is not vision threatening, and with proper management, resolution of redness and discharge is typically expected within 1–2 weeks. When inflammation is severe or long-standing, the papillae may remain.

**Fig. 4.24.5** Conjunctival injection, corneal pannus, and punctate keratitis seen in contact lens–induced superior limbic keratoconjunctivitis.

### Superior Limbic Keratoconjunctivitis

Contact lens wear has been associated with injection and fluorescein staining of the superior bulbar conjunctiva, termed *superior limbic keratoconjunctivitis* (SLK). Patients may experience tearing, burning, foreign body sensation, and lens intolerance. The appearance is similar to idiopathic SLK described by Theodore in 1963,<sup>22</sup> which, interestingly, is sometimes treated with therapeutic lenses.<sup>23</sup> SLK in contact lens wearers has been associated with preservatives in contact lens solutions, but mechanical irritation from poor-fitting contact lenses may also be a factor.

In contact lens–associated SLK, the superior corneal epithelium is irregular with a micropannus and punctate staining (Fig. 4.24.5). A papillary reaction is often present on the superior tarsal conjunctiva, but the papillae tend to be smaller than those seen in GPC. Discontinuation of lens wear and topical lubrication is generally effective, but resolution may take weeks or months. Punctal occlusion may aid in resolution of symptoms.<sup>24</sup> Patients can return to lens wear after being refitted with new lenses and switching to hydrogen peroxide disinfection, and nonpreserved saline daily disposable lenses are another option for SLK patients.

## CONDITIONS REFLECTING METABOLIC CHALLENGE

### Corneal Hypoxia and Edema

Contact lenses create a physical barrier that impairs the cornea's natural ability to harvest oxygen from the atmosphere and may lead to corneal hypoxia. With continued hypoxia, cell death occurs, leading to erosions or necrosis and desquamation and causing decreased vision, pain, tearing, and photoallodynia.<sup>25</sup> Chronic low-grade hypoxia causes subtle changes in corneal physiology and structure. Examination findings may include central epithelial microcysts and edema ("Sattler's veil"), neovascularization (Fig. 4.24.6), stromal thickening and striae, and endothelial blebs<sup>26</sup> (Fig. 4.24.7). The corneal edema can fluctuate throughout the day, typically being worse in the morning. Lens wear should be discontinued until the edema resolves and then a high-Dk lens should be substituted.<sup>25,27</sup>

### Neovascularization

As previously mentioned, chronic low-grade hypoxia can cause corneal neovascularization. Hypoxia results in the accumulation of lactic acid and carbon dioxide, which stimulates vascular ingrowth<sup>26,28</sup> and hypoxic dilation of limbal vessels.<sup>29</sup> Although typically associated with low-Dk hydrogel lenses, neovascularization may also be seen with poorly fit RGP lenses because of chronic irritation, such as in vascularized limbal keratitis (VLK). VLK lesions appear as an elevated, opaque mass at the limbal–epithelial junction with superficial and deep vascularization.<sup>30</sup>

Superficial neovascular changes (pannus) are common in patients wearing soft, low-Dk lenses, and may be acceptable if the pannus is stable and it extends less than 1.5 mm onto the cornea. This superficial neovascularization is likely caused by angiogenic factors released in response to chronic limbal trauma and hypoxia. Vascular ingrowth into the corneal

**Fig. 4.24.6** Chronic hypoxia associated with contact lens wear can lead to corneal neovascularization.

**Fig. 4.24.7** Stromal thickening and faint endothelial striae are seen in a patient with chronic stromal edema.

stroma is more worrisome because these vessels can lead to lipid exudation, scarring, and intracorneal hemorrhages (Fig. 4.24.8). Stromal neovascular changes or superficial neovascularization that extends more than 2 mm onto the cornea should be considered abnormal and unacceptable. When the patient is refitted with high-Dk lenses, reduction of the abnormal vessels and limbal erythema is expected.<sup>31-33</sup>

### Limbal Stem Cell Deficiency

Limbal stem cell deficiency (LSCD) is caused by the loss of function of corneal epithelial cell precursors. Contact lens-associated LSCD was first referred to as *contact lens-induced keratopathy* (CLIK), in which the keratoconjunctivitis progressed to diffuse corneal scarring and vascularization, sometimes requiring penetrating keratoplasty.<sup>34</sup> Bowman's membrane is damaged and replaced by fibrous scar tissue with deep stromal vascularization<sup>35</sup> (Fig. 4.24.9).

The clinical picture of contact lens-induced LSCD is typically milder than other causes of LSCD as evidenced by the finding that 71.4% of patients with contact lens-induced LSCD are asymptomatic.<sup>36</sup> The slit-lamp exam in contact lens-induced LSCD demonstrates whorl-like epitheliopathy, conjunctivalization of the cornea, absence of palisades of Vogt, and late fluorescein staining.<sup>37</sup> As the disease progresses, findings include pannus, epithelial defects, scarring, and vision loss.<sup>38</sup> Treatment of contact

**Fig. 4.24.8** Corneal neovascularization can, on rare occasion, lead to an intrastromal hemorrhage, seen at the 2 o'clock position in this patient.

**Fig. 4.24.9** Contact lens-induced keratopathy (CLIK) progresses to diffuse corneal scarring and vascularization, seen in this view with areas of superior thickening, fibrosis, and neovascularization.

lens-induced LSCD depends largely on the severity of disease. Initial medical treatment includes discontinuation of wear and optimization of the tear film and ocular surface via a combination of artificial tears, topical corticosteroid, topical cyclosporine, topical vitamin A, punctal occlusion, and oral doxycycline.<sup>39,40</sup> If maximal medical therapy fails, surgical options include mechanical removal of conjunctivalized corneal epithelium, amniotic membrane transplantation, and limbal autograft or allogeneic transplantation.<sup>41-44</sup>

### Abrasions

Corneal abrasions are epithelial defects caused by trauma to the ocular surface. Abrasions frequently occur with contact lens use during the insertion or removal process and are caused by fingernails or the lens itself. Abrasions allow bacteria access to the corneal stroma, and therefore careful evaluation for MK is warranted when there is an abrasion in the context of contact lens wear. In the setting of contact lens use, recommended treatment of corneal abrasion is a broad-spectrum antibiotic, such as a fluoroquinolone or aminoglycoside, which offers prophylaxis against *Pseudomonas*. Patching and topical corticosteroids have no proven benefit and should not be used in contact lens-associated corneal abrasions.<sup>45-47</sup>

## CORNEAL INFLAMMATORY EVENTS AND MICROBIAL KERATITIS

There is lack of standardization in the literature and discourse surrounding corneal opacities with or without an overlying defect.<sup>48–50</sup> It is common for the terms *ulcer*, *infiltrate*, *sterile infiltrate*, *presumed microbial keratitis*, and so on to be used imprecisely; the authors of this chapter will therefore use a classification system first proposed by Efron et al.<sup>51</sup> This system separates the spectrum of clinical findings into two distinct entities: CIEs and MK.

CIEs include an epithelial or subepithelial infiltrate, with or without an epithelial defect, which improves in the absence of treatment and typically does not cause scarring. Treatment of CIEs may be hastened by antibiotics and/or corticosteroids. However, MK is an epithelial defect with stromal involvement or tissue loss (also referred to as “crater”), typically leaves a scar, has a presumed or confirmed pathogen and requires intensive treatment with antimicrobials. It is acceptable to use the term “ulcer” when referring to MK but not to CIEs.

### The Role of Lens Care Systems

For several years, multipurpose solutions (MPSs) have been the most popular lens care products.<sup>52</sup> They may contain surfactant cleaners, disinfecting agents, preservatives, and polymers or conditioners to make the contact lens more comfortable. The disinfecting component must contain antimicrobial agents sufficient to destroy micro-organisms. Despite approval by the U.S. Food and Drug Administration (FDA) and the popularity of MPS solutions, recent outbreaks of MK have focused attention on lens care. Studies also suggest other problems with MPS care systems because some solutions can, in fact, increase the binding of *Pseudomonas* to epithelial cells and decrease the rate of epithelial cell exfoliation.<sup>53</sup> Polyhexamethylene biguanide (PHMB)-based systems used with FDA group II lenses (high water, nonionic) resulted in increased corneal staining, and biguanides used with group IV lenses (high water, ionic) also increased staining and decreased biocide efficacy.<sup>54,55</sup> Lens wearers with solution-associated corneal staining were significantly more likely to develop corneal infiltrates.<sup>56</sup> In general, hydrogen peroxide care systems appear to have the best profile for disinfection of lenses and the lowest incidence of CIEs and corneal staining.<sup>57</sup>

In addition, lens handling greatly increases the incidence of lens contamination, with more than half the lenses removed aseptically from the eye showing microbial contamination. Studies have shown that greater than 50% of lens cases are contaminated. All types of care solutions can become contaminated, including up to 30% of preserved solutions.<sup>58</sup> Not surprisingly, those who wear contact lenses infrequently had a higher contamination rate. Rinsing lenses with saline or MPS appears to be effective in reducing contamination.<sup>59</sup> Use of daily disposable lenses is a way to avoid contamination and is associated with lower complication rates compared with other modes of daily soft lens wear.<sup>60</sup>

### Corneal Inflammatory Events

Contact lens-related CIEs range from small, asymptomatic lesions to large opacities that obscure vision. The opaque lesions are caused by polymorphonuclear and mononuclear leukocyte recruitment to the cornea and are likely host response to commensal organisms or lens-related bacteria.<sup>29,61</sup> Bacteria can form a biofilm on the surface of the lens or the lens case, and one study found that more than 70% of the risk for CIEs was related to the exposure to the lens biofilm.<sup>62</sup> Multiple other causes, including hypoxia, retrolental debris, and staphylococcal immune complexes, have been proposed and investigated.<sup>63–66</sup> The epithelium is usually intact but may show overlying superficial punctate keratitis, and the anterior chamber shows only minimal reaction.<sup>67–69</sup> Symptoms typically include irritation, pain, foreign body sensation, photolodnyia, and tearing.

The true incidence and significance of peripheral infiltrates is an area of ongoing study and debate. Sankaridurg et al. found that 1.6% of asymptomatic patients with no history of contact lens wear had corneal infiltrates at the start of a study comparing spectacle wear and daily disposable lenses. Asymptomatic infiltrates were seen in spectacle wearers at a rate of 11.3 events per 100 years of wear compared with 20.5 events per 100 years in wearers of daily disposable lenses. The daily disposable group had 2.5 symptomatic peripheral ulcers events, but no events were noted in the spectacle group.<sup>70</sup> Several other studies have reported the incidence of sterile peripheral infiltrates in users of extended-wear disposable lenses to be equal to or higher than daily wear.<sup>71–73</sup>

A large study of 6245 lens wearers found lens-related CIE in 159 patients (2.5%). Risk factors included age  $\leq 25$  years or less and greater than 50 years; refractive error greater than +5.00 diopters (D); smoking; and failure to maintain prescribed wear schedule.<sup>74</sup> Further, a meta-analysis of published and presented studies (1991–2006) found a twofold higher risk for CIEs in users of SH lenses worn for up to 30 days compared with low-Dk extended-wear lenses worn for 7 days. However, it was not clear if the increased risk was related to the lens material or the wear schedule.<sup>75</sup>

The Moorfields Eye Hospital (London, UK) compared daily disposable, silicone hydrogel, and planned replacement lenses and found a significantly reduced risk of toxic/hypersensitivity reactions, papillary conjunctivitis, and metabolic disorders for daily disposables but an increased risk of sterile keratitis and mechanical disorders. Silicone hydrogels did not cause hypoxic complications but had an increased risk of sterile keratitis, mechanical disorders, and nonulcerative complications compared to conventional soft lenses.<sup>75</sup> Risk factors for CIEs included overnight wear, more days of lens wear per week, poor hand hygiene, smoking, and inexperience with use. The authors concluded neither daily disposable lenses nor silicone hydrogels reduced the overall risk of acute nonulcerative events.<sup>75</sup> Corneal scrape and cultures can be obtained to evaluate for infectious etiologies and should especially be acquired if the infiltrate increases, vision is affected, or if the infiltrate is large ( $>1$  mm).<sup>76</sup> However, it is difficult to rely only on culture data to guide clinical decision making. Reported cultures of “obvious” MK are positive 43%–86% of the time, yet one study of “sterile” peripheral infiltrates found positive cultures in 50% of the subset of patients.<sup>77–80</sup> Many clinicians believe that small peripheral infiltrates do not require cultures, but cultures on organisms have been performed, particularly if an epithelial defect is present.<sup>73,76</sup> When organisms are recovered, they tend to be less virulent than those associated with central ulcers. The most common isolate is staphylococcus spp., but even in the face of positive culture results, many authors believe that peripheral infiltrates are inflammatory because microorganisms are not recovered in most studies, and infiltrates often resolve with corticosteroid therapy alone.<sup>76,81</sup>

Discontinuation of lens wear is the first step in the treatment of CIEs. Depending on location and size of the infiltrate and the capacity for monitoring additional treatment options include topical, broad-spectrum antibiotics, topical corticosteroids, or a combination of the two. The clinical appearance can change rapidly, and most patients are seen in 24 hours with modification of therapy, as needed. After resolution, assessment of the patient's wear and replacement schedules, as well as their care regimen, should be made. Extended wear should be discouraged. Reduction of bioburden at the lid margins<sup>82</sup> and in lens cases, as well as a switch to daily disposable or hydrogen peroxide care system, should be considered.<sup>57</sup>

### Microbial Keratitis

Although the overall incidence is low, contact lens wear is now considered the major risk factor for MK, with about 65% of all new ulcers related to contact lens use.<sup>83,84</sup> MK can be sight threatening because of corneal scarring and is therefore important to differentiate early-stage MK from CIEs so as to not delay treatment.

The most important risk factor for MK is overnight or extended lens use,<sup>2,3,71,85–87</sup> followed by poor lens/lens case disinfection, smoking, lower socioeconomic class, and failure to wash hands.<sup>3,88–90</sup> It is surprising that the surge in disposable single-use contact lenses has not decreased the rates of MK; however, there has been a decrease in vision loss caused by MK in daily contact lens wearers.<sup>91</sup> Stapleton reported a higher incidence rate of MK with silicone hydrogel (SH) contact lenses compared to daily disposable, and higher rates of MK when SH contact lenses were worn overnight compared with conventional hydrogels.<sup>92</sup> Overall, daily disposable lenses are associated with less severe MK and are less likely to cause vision-impairing central MK.

Findings associated with MK include positive corneal culture results, continuous pain after discontinuation of wear, photolodnyia, purulent discharge (Fig. 4.24.10), conjunctival injection, epithelial staining, anterior chamber reaction<sup>67</sup> and corneal edema that surrounds an infiltrate. Stromal opacities in MK are usually larger than 1.5 mm and have overlying epithelial defect and purulent discharge. Multiple studies have demonstrated that pathogenic microorganisms, especially *Pseudomonas* spp., fungi, *Acanthamoeba*, and *Nocardia*, are the main causes and determinants of outcome in MK.<sup>93–101</sup>

Lee et al. found that Gram-positive bacteria are more prevalent in MK, whereas Gram-negative bacteria are more virulent.<sup>102</sup>

When MK ulcers are suspected, scraping, culture, and Gram staining must be performed. The solutions and the lens case should be

**Fig. 4.24.10** This *Fusarium* ulcer occurred in a contact lens wearer using the lens solution brand ReNu with MoistureLoc, which was subsequently withdrawn from the market.
